Dr. Emil Mayer, of New York, read a letter on Empyema of the Antrum of Highmore in Infants, in which, after noting that the literature on the subject was excessively meagre, he reported a case in his own practice in a child, 2½ years old, in whom the general symptoms noted were eversion of the right lower lid, fistulous opening in right cheek, from which pus exuded and a most penetrating odor from the right side of the nose. The child was operated on, and recovery took place without any difficulty. The writer concludes that it is established beyond doubt that empyema of the antrum of Highmore in young children is not merely caries or tuberculosis or an osteomyelitis, but is as distinct an affection as in later life.

Dr. H. H. Bryan, of Washington, reported a very interesting case of Abscess of the Frontal, Ethmoidal and Sphenoidal Sinuses which had been under his care for the last two years. He gave the different steps that he had pursued in the effort to relieve and cure this condition, but he has been forced to come to the conclusion that there is but one outcome of the condition, and that is pain, suffering and finally death coming to the relief, where medical and surgical measures have failed.

Dr. Carl Seiler, of Scranton, Pa., presented a paper on The Effects of Cinchonism Upon Vocalization and Articulations. He found in the first place that the ordinary tinnitus aurium due to middle ear disease never transgressed the limits of pitch from D 1 (297 vibrations as the lowest point to the F 2 (704 vibrations) as the highest, as near as it was possible for him to determine, and that these subjective noises although variable in quality or timbre had no appreciable effect upon vocalization or articulation, but that they would invariably and very materially effect the perception of sounds which had the same or nearly the same number of vibrations per second as the subjective noises of the patient. The subjective noises due to Quinine, Salicylate of Soda, Alcohol, Ether and many others, were invariably of a very high pitch varying from as low as the G 3 (1584 vibrations) to as high as (3960 vibrations) and often even higher. He also observed that any composite noises of high pitch not only interfered with the pronunciation of those consonants which according to the investigations of Helmholtz and others have for their characteristic sound a combination of high pitched sounds such as "th," "S," "Sh," "Z," and the like consonant sounds of articulate speech, but also caused them to be easily obliterated and consequently most difficult to appreciate and to be recognized by the ear.

Wyatt Wingrave, M. D., of London, Eng., 26 cases of tonsillotomy rash. This is somewhat similar to the (urgicæ) rash, that follows some operations in some cases. The eruption generally appears on the second or third day, either papular, roseolar or erythematous in type. It most frequently attacks the neck, chest and abdomen, sometimes extending to the face and extremities. The earliest appearance noted was the day following the operation, and the latest, the sixth day. Its duration is generally two or three days, but it may extend to five days. After reaching its maximum intensity, it rapidly disappears without desqu-

mation, but is sometimes associated with intense itching. It may occur at any age, the youngest of his cases being 14 months, and the oldest 23 years.

SECOND DAY.

Dr. Francke H. Bosworth, of New York, presented a paper on: "The Tonsils from a purely Clinical Point of View." In this, he takes the ground that the only healthy tonsil is one in which there is no hypertrophy, in other words, the tonsil that is manifest on inspection is not a normal one. He advises the removal of this tumor, as he would the tumor of any other kind that might present, whether benign, malignant or otherwise.

Dr. C. H. Knight, of New York, read a paper on Vocal Nodules. In this paper the writer takes the ground that the cause of these nodules of the vocal chords are due to some abnormal condition in the upper air tract, rather than to any abnormality either in the vocal chords themselves or in the larynx. He does not mean to say that there are no cases that could be ascribed to any other cause, but that the majority of these cases are due to the lesions higher up. He thinks that the nodule is the secondary condition, and not the primary one. He also thinks that the condition is more or less permanent, in spite of the fact that there are some authors that incline to the belief that they are transitory from over use.

A study of the proper application of intubation in chronic stenosis of the larynx, was the subject of a very able paper by Dr. W. K. Simpson, of New York. The writer divides these cases into three classes: First, those of gradual stenosis, of longer or shorter standing, in which immediate intubation is not necessary. Second, Those cases in which an acute exacerbation renders immediate intubation necessary in order to save life, and third, Those cases where it is desired to avoid wearing a tracheal canula.

In the first two classes of cases, unless a clear view of the larynx can be had and a positive knowledge of the immediate cause of the stenosis obtained, intubation is not to be thought of, but tracheotomy done instead. In doing a tracheotomy, it is well to do it as high as can be done with safety and then after the immediate symptoms are relieved it is well to intubate. An intubation tube may be worn for months without changing. The difficulty in retaining an intubation tube has been overcome by Dr. John Rogers, who has added to the original O'Dwyer tube a right angled tube which is allowed to protrude from the tracheal opening. This secondary tube, is added at the time of intubation, after the tube has been placed in position, and marked through the tracheal opening. As the tubes are made of hard rubber, it is a matter of only a short time.

Dr. C. C. Rice, of New York, read a very interesting paper on the subject of local treatment of the nasal mucous membrane in Hay Fever. After a very thorough and exhaustive review of the theories of the etiology of this troublesome disorder, he explained his new treatment. It is well known that there are sensitive areas in the nose, and that these are the primary causes of hay fever, is the belief of the writer. He takes the ground that if these sensitive areas are rendered less sensitive that a long step has been taken in the direction of the prevention of a recurrence of the fever. He was led to this line of reasoning by using a swab to smooth off some of the granulations in atrophic rhinitis. The method of treatment is to rub or scrub the mucous membrane of the nostrils all over, with some solution or even with simple cotton and establish a tolerancy of the nasal mucous membrane to the presence of the irritant. In all or nearly all of the cases that he has treated by this method, he had to accustom the membrane to the touch of the probe. The first applications were very apt to cause more or less violent attacks of sneezing or coughing. After a few applications, this intolerance passed away, and he was able to obliterate the sensibility very markedly. The applications were made every other day for the first month, and then twice a month after that, beginning four months before the time of the expected attack. The treatment was carried out until the time of attack had passed.

Dr. Makuen, of Philadelphia, Pa., read a paper on Cleft Palate and its relation to speech. This paper is one of those that cannot be abstracted, or even described to another. It was a very able paper in every respect, but from the very nature of the subject it is seen that there was much that

pertained to the sounds of the various vowels and consonants which can hardly be put into cold type.

Dr. A. W. DeRoaldes, of New Orleans, La., presented a paper on the subject of the use of the electro-magnet for the extraction of foreign bodies from the air passages. He also presented some instruments that he had had constructed for such use. He gave the results of the treatment of one case of foreign body in the trachea, in which, after having started to perform a tracheotomy the point of a large Haab magnet was brought near the wound, and the metallic object was immediately drawn out from its place of lodgement. In addition to this case, he had conducted a series of experiments on the cadaver, and had tabulated the results of these, that they might in a way be a guide in the future application of this method. This is the first time that the magnet has been brought to the notice of the profession, in such cases.

The following named were chosen as the officers of the Association for 1901-1902: President, J. W. Farlow, M. D., Boston, Mass.; first vice-president, J. W. Gleitsmann, M. D., New York City; second vice-president, D. B. Kyle, M. D., Philadelphia; secretary and treasurer, James E. Newcomb, M. D., 118 W. 69th St., New York City; librarian, Joseph H. Bryan, M. D., Washington, D. C.; council, Thomas R. French, M. D., Brooklyn; William E. Casselberry, M. D., Chicago; Samuel Johnson, M. D., Baltimore; Henry L. Swain, M. D., New Haven.

The next meeting of the Association will be held in Boston, Mass., in May, 1902.

GAZETTE MEDICALE DE PARIS.

March 16, 1901. (72me. Année, No. II).

1. Clinical Remarks on the Death of Napoleon the First. MARCEL BAUDOUIN.

1.—Many books have been written in which the last years of the great Napoleon have been depicted. Though many physicians examined and treated him, they drew different conclusions. He was ill during the four years before his death. Cancer would most probably have killed in that time. Stokoe had diagnosed chronic hepatic disease, and later abscess of the liver. This Baudouin, from the perusal of the books on the subject, believes to have been a perihepatitis, due to extension from the evident existing perigastritis. For Baudouin believes that Napoleon had an ulcer of the stomach, which caused his death by perforating. Hematemesis was present with fever off and on, and vomiting. There was no hypertrophy of the liver, nor any signs of cancer, while a gastric ulcer which had perforated was found near the pylorus at the autopsy. [M. O.]

April 6, 1901. (72me. Année, No. 14.)

1. The Pathogenic Agent in Acute Articular Rheumatism. PIERRE ACHALME.

1.—In 1891, and again in 1897, Achalme described an anaerobic bacillus found in cases of acute articular rheumatism. It resembles the bacillus anthracis, is obligately anaerobic, stains with Gram's or Claudius' method, lives only between 21° and 45° C., contains ovoid spores, causes clotting of milk with gas production, and acts with varied virulence in animals. It can best assimilate nitrogen in the creatinic bases. It easily liquifies gelatin. Its diastase, which breaks up albumenoids, is a trypsin, the action of which is hindered by the presence of acids. Yet with carbohydrates the bacillus causes the formation of butyric, acetic, and lactic acids, and the fermentation of the sugars and starches. This fermentative action prevents the trypsin from destroying the fibrin or albumen, and limits the life of the organism: for sporulation never occurs in acid media. In some cases the bacillus has been found in the synovial fluid, the blood-clots in the heart, and the myocardium. In others it cannot be found. Achalme does not claim that it is a specific bacillus. He believes it is found in healthy individuals, and can be the cause of acute articular rheumatism or puerperal fever; or in animals, of abscess, gangrene, appendicitis, etc. It causes that vague form of rheumatism in which there are few arthritic, mainly cardiac symptoms. In these cases there is often an eruption, scarlatiniform in character. The bacillus causes some putrefaction, and the action of the salicylates in curing the condition is explained by their removing the products of putrefaction in salicyluric acid. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

World's Heaviest Baby.—Probably the heaviest baby in the world for her age is Francisca Lillian Minnis, daughter of George Minnis, of Atlantic, Crawford county, Pa. She is 8 months old, her bust measure is 31 inches, weighs 51½ pounds and is in perfect health. Her parents are below the average in height and weight.

State Funds for Charity.—Twenty-four bills for private charities were reported in the House at Harrisburg, Pa., May 27, from the Appropriations Committee, as follows:

Pennsylvania Home for Blind, Philadelphia, \$25,000.
Evangelical Home for Aged, Philadelphia, \$1000.
Bethesda Home, Pittsburg, \$5000.
Home for Aged, Easton, \$2000.
Rush Hospital, Philadelphia, \$10,000.
Midnight Mission, Philadelphia, \$2000.
Easton Hospital, \$12,000.
Children's Aid Society, Philadelphia, \$10,000.
Home for Aged, Philadelphia, \$4000.
West Philadelphia Hospital for Women, \$2500.
Brookville Memorial Home, \$7000.
Wagner Free Institute, Philadelphia, \$2000.
Lying-in Charity Hospital, Philadelphia, \$15,000.
Maternity Hospital, Philadelphia, \$5000.
Old Ladies' Home, Philadelphia, \$4000.
Home of Friendless, Harrisburg, \$2500.
Howard Hospital, Philadelphia, \$5000.
Home for Aged Veterans, Philadelphia, \$6000.
Union Home for Old Ladies, Philadelphia, \$4000.
Home for Widows, Lebanon, \$2000.
Children's Aid Society, Pittsburg, \$10,000.
Home for Infants, Philadelphia, \$4000.
Asylum for Indigent Widows, Philadelphia, \$5000.
Colony Farm, \$10,000.

Jefferson Medical College.—The class of 1891 of the Jefferson Medical College will hold a re-union in Philadelphia on June 27, 28 and 29. All graduates, and especially members of the Classes of 1890 and 1892, are cordially invited to be present.

Almshouse Removal Urged by Citizens.—Representatives of nearly every medical college and society in the city, of civic organizations and many well known citizens appeared before Councils' Committee on Charities and Correction, at its public meeting June 3rd, to recommend the separation of the Almshouse and insane departments of Blockley from the Philadelphia Hospital. The chief arguments advanced were that the three institutions are overcrowded, and that the requirements of modern science demand open air and work for the insane. Chairman H. R. Kneass, of the committee, presided. At the close of the meeting a resolution was adopted authorizing the Department of Charities and Correction to select suitable sites for the Almshouse and insane departments, and to report to the committee for further action. Dr. John V. Shoemaker, President of the Department of Charities and Correction, showed the lack of accommodations for patients, and spoke of the feeling of abhorrence with which many persons in need of medical aid regard the Philadelphia Hospital, simply because it is connected with the Almshouse. If the two departments were separated, he thought the city would be able more widely to extend its usefulness.

Vital Statistics of Philadelphia for the week ending June 1, 1901:

NEW JERSEY.

Proposed Memorial to Dr. Bartine.—The erection of a tablet is proposed by some of the prominent citizens of Merchantville, N. J., to perpetuate the memory of the late Dr. D. H. Bartine, who practiced his profession in that town for thirty-five years. The tablet is to cost not less than \$1000.

NEW YORK.

Cornell University has established an infirmary exclusively for its students. The building which is to be used for this purpose was formerly the home of the late H. W. Sage, who donated the building and \$100,000 for the infirmary.

Institute for Medical Research.—Having conferred with many eminent pathologists as to the best method of setting on foot an original scientific research into the problems of medicine and hygiene, John D. Rockefeller has placed at the disposal of a body of prominent medical men \$200,000, to be available for immediate expenditure by an association incorporated under the name of "The Rockefeller Institute for Medical Research." The home of this institute, with such laboratories, staff and equipment as may be found necessary, will be located in New York City. The officers and Board of Directors have already been chosen. The list of officers is as follows: Dr. William H. Welch, Baltimore, president; Dr. T. M. Prudden, vice-president; Dr. L. Emmett Holt, secretary, and Dr. C. A. Herter, New York, treasurer. The directors are: Dr. H. M. Priggs, New York City; Dr. Theobald Smith, of Boston; Dr. Simon Flexner, Philadelphia. Indications are that the \$200,000 which Mr. Rockefeller has given as the capital of the new institute is a trifling sum compared to what he contemplates giving ultimately to the same cause. The work will be done at Columbia University, Harvard University, the University of Chicago, the University of Michigan, the University of Pennsylvania, Johns Hopkins University, McGill University, of Montreal, and the headquarters of the New York Health Department. The directors of the new Rockefeller Institute will have supervision over it, but it will be performed by physicians whom they will employ, and who will work more or less independently in the different places mentioned. The heads of the various pathological laboratories will have general charge of the investigation, whether they happen to be directors of the institute or not. Periodically the directors, whose joint judgment will be the sole regulator of the expenditure of the \$200,000 provided, will meet to discuss the result of the work, and will jointly give out the information which it may have developed through the original channels. The work may go on for a year or two before definite plans are made for a permanent institution. The investigation of the country's milk supply will be the first important problem of which the directors will take hold. Their work is to be chiefly bacteriological.

Montefiore Home for Consumptives Dedicated.—The county home for consumptives of the Montefiore Home for Chronic Invalids, was dedicated May 30th at Bedford Station, N. Y. After preliminary exercises the keys were

presented to Jacob H. Schiff, president of the home, by Isaac Eppinger, chairman of the building committee, Mr. Schiff giving a history of the home. Theodore Roosevelt, vice-president of the United States, was then introduced and spoke of the magnificent work of the home.

St. Mark's Hospital.—At a recent meeting of the Society of the Alumni of St. Mark's Hospital of New York the following officers were elected for the ensuing year: Nicholas R. Dann, M. D., president; Conger F. Smith, M. D., vice-president; Ephriam K. Dowd, M. D., treasurer; Harry G. Watson, M. D., secretary.

NEW ENGLAND.

The American Laryngological Society.—At the meeting of the American Laryngological Society held at Yale University on May 28, the committee on nominations presented a report recommending that the following be the officers for the ensuing year: President, J. W. Farlow, of Boston; first vice-president, W. J. Gleitsmann of New York; second vice-president, D. Braden Kyle, of Philadelphia; secretary and treasurer, James E. Newcomb, of New York; librarian, J. H. Bryan, of Washington, D. C. This report will be acted on this morning, with a recommendation also that the next session of the society be held in Boston in June, 1902. Papers on technical subjects were presented yesterday by J. W. Geistmann, T. R. French, F. H. Bosworth, C. H. Knight, W. K. Simpson and Wyatt Wingrave of New York, A. W. Watson of Philadelphia and J. H. Goodale of Boston.

WESTERN STATES.

St. Peter's Hospital in Helena, Montana, was recently partly destroyed by fire. No one was injured, and the loss, which was \$10,000, was fully covered by insurance.

Military Surgeons Favor the Canteen.—The Association of Military Surgeons in session at St. Paul, Minn., on May 31, unanimously passed a resolution in favor of repealing the anti-canteen law.

Smallpox in Wisconsin.—Smallpox has caused the indefinite postponement of the High School commencement at Chippewa Falls, Wis.

Leprosy in Wisconsin.—Two cases of well-developed leprosy have been discovered in Tustin, Wis. A mother and her daughter are the victims. The cases are being investigated.

SOUTHERN STATES.

Elected Professor of Dental Pathology.—Dr. W. H. McGehee has been elected Professor of Dental Pathology, vice Dr. Ernest Walker, resigned, in the University College of Medicine, Richmond, Va.

Richmond.—The affairs of the Southwestern Insane Asylum in regard to its medical management, are now under investigation.

Mosquito Pest.—The Board of Health of the city of Galveston, Tex., is arranging for a large supply of oil from the Beaumont wells to be used in fighting mosquitos. The oil will be distributed in all the stagnant pools in the city, sprinkled on the surface of water in the gutters, and distributed free to owners of open cisterns for use in destroying mosquitos and the fever-breeding germs which collect in the ponds. Experiments made by the Board of Health have demonstrated the virtue of crude oil as a sanitary measure if properly used and petroleum water as healthful and nourishing for drinking purposes.

Dr. Richardson Elected.—Dr. Charles W. Richardson, of Washington, D. C., was elected president of the American Laryngological and Otological Society at its meeting in Baltimore, Md., May 26.

OBITUARY.

Dr. James R. Bayley, at Newport, Ore., on May 24, aged 82 years.—Dr. Charles St. John, at Pericale, Luzon, on May 22.—Dr. Dwight Mereness, at Milwaukee, Wis., on May 29, aged 41 years.—Dr. D. C. Thomas, at Adrian, Mich., on May 30, aged 66 years.—Dr. John L. Feeny, at Staten Island, N. Y., on June 1.—Dr. Edmond Beale, at Philadelphia,

Pa., on June 1, aged 81 years.—Dr. R. B. Archibald, at Purdy, Mo., on May 31, aged 55 years.

Dr. George B. Noyes, at Waupaca, Wis., on May 25, aged 54 years.—Dr. I. P. Hubert Larose, at Indian Orchard, Mass., on May 28, aged 31 years.—Dr. J. A. Heald, at Denton, Tex., on May 29, aged 80 years.—Dr. J. W. Allen, at Guthrie, Ky., on May 28, aged 45 years.—Dr. John E. Comfort, at New York City, on May 29, aged 64 years.

Dr. Edward Sultan, at St. Louis, Mo., on May 15.—Dr. John A. Wells, Englewood, N. J., on May 21, aged 45 years. Dr. George Woodson Scott, near Madison Run, Va., on May 14, aged 35 years; Dr. Whitcomb Pratt, at Richmond, Va., on May 16, aged 52 years; Dr. Jacob Derrickson, at Philadelphia, Pa., on May 17, aged 75 years; Dr. Charles D. Sherman, at Lancaster, Pa., on May 18, aged 52 years; Dr. A. D. Gibson, at South Omaha, Neb., on May 16, aged 78 years; Dr. John H. Bruere, at St. Louis, Mo., on May 16, aged 34 years.

Changes in the Medical Corps of the Navy for Week ended June 1, 1901.

DR. J. H. IDEN, appointed assistant surgeon in the Navy, from May 4, 1901—May 25.

MEDICAL DIRECTOR W. S. DIXON, commissioned medical director from April 28, 1901—May 25.

MEDICAL INSPECTOR C. G. HERNDON, commissioned medical inspector, from April 28, 1901—May 25.

P. A. SURGEON E. V. ARMSTRONG, detached from Vermont, and ordered to Key West Naval Station for duty at Dry Tortugas—May 25.

ASSISTANT SURGEON T. M. LIPPITT, ordered to the Washington Navy Yard, June 1—May 28.

ASSISTANT SURGEON R. B. WILLIAMS, detached from duty at Dry Tortugas, and ordered home to be in readiness for sea duty—May 25.

ASSISTANT SURGEON J. H. IDEN, ordered to Naval Hospital, Chelsea, Mass., for duty—May 25.

PAST ASSISTANT SURGEON J. F. COSTIGAN, detached from the Yorktown and ordered home. Resignation to be accepted after arrival—May 29.

ASSISTANT SURGEON W. M. GARTON, detached from the Washington Navy Yard, June 1, and ordered to the Indiana—May 29.

ASSISTANT SURGEON H. O. SHIFFERT, ordered to the Nashville—May 29.

ASSISTANT SURGEON E. THOMPSON, ordered to the Solace—May 29.

ASSISTANT SURGEON R. K. McCLANAHAN, ordered to the Culgoa—May 29.

PHARMACIST J. COWAN, detached from the Manila and Cavite Naval Station, and ordered to Naval Hospital, Yokohama, Japan—May 29.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended June 1, 1901:

SMALLPOX—UNITED STATES AND INSULAR.

MISCELLANY.

The Plague is becoming very widespread in its distribution. It has appeared in Rio de Janeiro, in Cape Colony, and has been increasing. The same is true of Mauritius. It has appeared in West Australia and Hong Kong. It is present in Karigagua, in Russia, but is decreasing there. In Argentine a number of cases occurred in San Nicolas, and suspected cases appeared in Belleville and Marious Jaurez, in Cordova Province.

Leprosy in the United States.—According to scientific government investigations directed from Washington for several months, there are at least 275 cases of leprosy in the United States. That number have been reported, but it is thought probable that the real number is nearer a thousand. For various reasons, physicians who have cases of this disease in many instances fail or refuse to report them. But the number reported is sufficiently large to occasion some alarm. Seventy-four of the known cases are in New Orleans, chiefly among the Italian population. There are twenty-three in Minnesota, mostly among Scandinavians in the rural settlements. There are fifteen cases in North Dakota, and two in South Dakota, among the same people. So far as has been ascertained, there are none in Michigan or in Indiana; Chicago has five cases, New York six, Boston none. The figures now compiling represent a great deal of careful work. A circular letter was sent from Washington to every city and county physician, every health officer, ever responsible head of a hospital, in the country. It called for volunteer information covering cases of leprosy in the community in question; the name of the leprosy person, the sex, age, social condition, place of residence—whether town or country—and name of attending physician. In all, 8,000 of these letters have gone out; replies have thus far been received from only 2,000 of them. There may be several times 275 cases in the 6000 districts from which thus far no replies have come. It is the intention of those who are compiling the figures to make the report to Congress, including such recommendations as may seem warranted. One recommendation will be for the erection of two large Government hospitals for lepers, one in the South and the other in the North. Eminent physicians have at different times been before committees of Congress in the interest of the erection of leper hospitals, but nothing came of these visits, the Government having no reliable data covering the prevalence of the

disease. Next winter, however, with full information on the subject, it is believed that Congress will act promptly. It is noteworthy that nearly all the 275 reported victims are foreigners. The Scandinavians seemed peculiarly susceptible to the disease. They either had it when they landed in America, or contracted it soon after landing. Every one of the cases in the Dakotas and Minnesota is in the country, rather remote even from the small towns. The disease seems to be spreading most rapidly in Louisiana, and for several years there has been agitation there in favor of effective public supervision and control of all leprosy patients, either by the State or by the Federal Government.

Alaska Smallpox Epidemic.—The steamer Victorian from Skagway, reports considerable excitement in the north, caused by the smallpox epidemic, and various settlements are taking every precaution to check and wipe out the disease. At Skagway the Indians were driven out of the city and a strong guard placed around the town to prevent their return. One or two cases of the disease exist among employes of the Treadwell mine on Douglas island, and according to reports it is believed that the big mining plant will have to shut down until the disease is stamped out.

Plague in Manila.—All vessels leaving Manila for other Island ports will be required to conform to the regulations contained in the following circular:

Manila, P. I., March 27, 1901.

Sir:—In view of the increase of plague in Manila and in order to protect other ports in the Philippines from the introduction of the disease, as well as to lessen the danger to vessels of infection and the liability to quarantine, all vessels leaving Manila for other island ports will be required to conform to the following regulations:

All vessels will be required to secure bills of health before sailing, and this will only be issued after an examination of the crew and passengers, and no passengers will be allowed to embark after this inspection.

Any passengers found sick on inspection will not be allowed to sail on that trip.

All passengers, with their baggage, and crew must be on board three hours before the time fixed for sailing.

The office must be notified three hours before the time fixed for sailing of vessel, so as to afford ample time for inspection and disinfection of baggage and allow the vessel to leave on schedule time.

You will notify all deck passengers that their baggage will be disinfected on board of vessel, and that no mattresses or pillows can be taken. After this disinfection the captain of the ship must take charge of the baggage and see that it is kept closed for twenty-four hours, or until the end of the passengers' voyage in case this is less than twenty-four hours.

This regulation will go into effect on April 1, 1901, and continue until further notice. Thanking you for your co-operation.

Respectfully,
J. C. PERRY,
Passed Assistant Surgeon, U. S. M. H. S.,
Chief Quarantine Officer for the Philippine Islands.

Plague in China.—A communication from Robert M. McWade, U. S. Consul, states that: The plague has again begun its ravages in Canton and vicinity, as well as in other parts of the Kwangtung province. As the authorities are averse to the full facts of the ravages of the scourge being made public, no official records are kept and, consequently, no adequate idea can be found or anything like accurate estimates given of the number of its victims or the extent of its ramifications. He is satisfied, however, that the cases in Canton are few in number. In the large village of Chan Tsin, about 12 miles west of Canton, the plague is prevalent, from 20 to 30 deaths occurring there daily for the last two weeks. This village has from 3,000 to 4,000 population. Some of the villages in the Shun Tak district are also infected, and so is the city of Fatshan, which has a population of over 500,000. The filthy condition of the public streets and byways and of the residences of the lower classes is mainly the cause of the reappearance of this awful disease.

A Useful Fly.—Experimenters of the United States Government saw one dragonfly eat up 800 mosquitoes in an hour, and it is now proposed to breed the "darning needle" on a large scale to see if they cannot be made sufficiently numerous to kill the mosquitoes responsible for propagating diseases.

Abstracts of Papers and Discussions at the Annual Meeting of the American Surgical Association, held in Baltimore on May 7th, 8th and 9th, 1901, the President, Dr. Roswell Park, of Baltimore, in the Chair.

(Continued from Page 1034.)

Dr. Eugene L. Opie, of Baltimore, in discussing Dr. Robson's paper on pancreatitis commented on the relation of gall-stones to the disease under discussion. He considered that there are two mechanisms, which explain this association, due to the anatomical features of the region. As to acute hemorrhagic pancreatitis he stated that a variety of irritating substances, when injected into the pancreas of animals, will produce this lesion and referred to the experiments of Flexner, who had injected artificial gastric juice, acids, alkalies and dilute formalin, to prove the fact. Another cause of hemorrhagic pancreatitis he believed to be the penetration of bile into the pancreas, which will confirm the fact of the relation between pancreatitis and gall-stones. It seems to be true that in the cases in which chronic interstitial pancreatitis accompanies gall-stones in the common duct, the pancreatitis, which has been at times mistaken for malignant disease of the gland, is the result of this obstruction.

Dr. Elliott, of Boston, in discussing Dr. Robson's paper on pancreatitis referred to the association of the disease with gall-stones, together with the relation of jaundice to these conditions, while theoretically, if the common duct was not blocked, there would be no jaundice, yet practically with stones only in the gall bladder jaundice is frequently present. Cases were cited where these conditions were true and where malignant disease had been diagnosed, although not present.

Dr. George R. Fowler, of Brooklyn, in discussing Dr. Robson's paper on Pancreatitis, reported three cases with symptoms and treatment, two of which recovered, while the third died. He laid particular stress on the collapse which occurred in his cases, in one being so bad that operation had to be put off several times.

Dr. Carson, of St. Louis, gave the details of a case occurring in his practice, of induration of the pancreas associated with jaundice. After operation the patient made a good recovery.

Dr. W. L. Estes, of Easton, Pennsylvania, reported two cases of operation with recovery, one of chronic interstitial pancreatitis simulating carcinoma and the other following an abdominal injury.

Dr. Leonard Freeman, of Denver, reported a case of jaundice, which he had believed to be due to gall-stones, and stated it had not occurred to him that pancreatic disease was probably the cause, although he had no doubt such was the case.

Dr. Robson closed the discussion and stated that he had never seen such marked and frequent attacks of collapse as those mentioned by Dr. Fowler. He reported one case where the collapsed condition of the patient had prevented operation and death had ensued, and he believed that it was a common symptom, although not to the extent in individual cases, observed by Dr. Fowler. He felt that the bile probably offered an explanation for many cases of hemorrhagic pancreatitis and he believed the infected nature of the bile was often the most important factor.

He referred briefly to Dr. Opie's specimens and expressed himself as much pleased with Dr. Brewer's description of the anatomy of the region.

Dr. A. W. Mayo Robson, of Leeds, England, read a paper entitled "The Surgical Treatment of Chronic Ulcer of the Stomach" and stated that the treatment of these cases is at first essentially medical. He compared the treatment of ulcer of the stomach with that of ulcer of the leg and particularly referred to the tendency to relapses. Twenty-three affections were referred to as complications of the condition, which were looked upon as serious menaces to the treatment of ulcer. He believes that about 25% of cases of gastric ulcer treated medically, died, while only about 16% treated surgically died, according to statistics a year ago, but at the present time, while the percentage death rate in cases treated medically remains about the same it has been reduced to 5% under surgical treatment. A number of operations were mentioned from which one could take his choice and great stress was laid upon the importance of the proper preparation of the patient before operation. Each operation was described in some detail

and cases illustrating each form of operation, together with the results obtained, were quoted. The number of operations performed by the author, divided up according to the number performed of each kind were given and the method he employs in stomach and other operations involving the making of an anastomotic opening between the hollow viscera was described. The author demonstrated the method which consisted practically of the employment of a method of suturing over a decalcified bone bobbin.

The original article was published in the *Philadelphia Medical Journal* of May 25, 1901.

The advantages claimed for the method are:

1. That it secures the opening, being of the exact size intended and that there is no possibility of the passage being made too small by the drawing up of the sutures before the knots are tightened.
2. That it secures an immediately patent channel between the two anastomosed viscera.
3. That the bobbin protects for from 24 to 48 hours the new line of union from pressure and from the irritation of the visceral contents.
4. That it facilitates the application of the sutures and so adds to the expedition of union by suture.
5. That no foreign material is left in the alimentary canal, which may irritate or cause subsequent trouble, for the bobbin rapidly dissolves in the alimentary juices.
6. That the method has now been proved by ample experience to be rapid, easy, efficient and safe.

The discussion of the foregoing paper was opened by Dr. William J. Mayo, of Rochester, Minnesota, who considered at some length the treatment of open ulcer of the stomach by gastroenterostomy, which he considered the most generally indicated operation for this condition in view of the following reasons:—

1. The varying extent and reasonable probability that more than one ulcer exists.
2. The common location of the ulceration.
3. The impossibility of locating the exact site of the ulcer in many cases.

In some few cases, presenting special features, he believed that excision or other form of surgical procedure is indicated.

The symptoms, he stated, depend somewhat upon the situation of the ulcer, the most common location being near the pylorus, which position may introduce certain mechanical features, and in the relief of these secondary phenomena in his opinion the operation achieves its triumphs. The relief of hyperacidity and a prompt emptying of the ingesta, preventing irritation and aiding nutrition is secured by gastroenterostomy.

Reference was made to the fact that the earlier reports on this subject demonstrate the existence at that time of a belief that the stomach was always contracted, but later reports have proven the error of considering this a fixed condition, although it is no doubt true in a majority of cases. In acute ulcer the stomach is usually small, and if the ulcer is not in the vicinity of the outlet, it will probably remain so. On the contrary, it is during the healing process that many ulcers in the pyloric region become most troublesome.

Ulcers in this situation are often extensive, and in chronic cases, perhaps but partly cicatrized, and obstruction of the pyloric orifice may take place by distortion or narrowing of the opening, irregular symptoms of the unhealed portion of the ulcer being manifest, in addition to the dilatation. In these cases periods of health alternate with symptoms of open ulcer, which are later followed by signs of open ulcer in a stomach more or less dilated. Most of the cases when once cicatrized remain healed, although a few sometimes develop into open ulcer. While the capacity of the stomach is not usually materially altered, in cases of gastric ulcer, when this condition does exist, it has a surgical significance.

He then made a comparison of the results of gastroenterostomy in (1) ulcers in the pyloric region with a normal or enlarged stomach, and (2) ulcers in a contracted stomach, and stated that in cases coming under the first group gastroenterostomy is the operation of choice, as it delivers the ingesta at a point sufficiently remote from the disease to prevent irritation, and the healing process is not interfered with and develops rapidly. Immediate and satisfactory relief for the mechanical condition is obtained, and in five gastroenterostomies performed under his observation all were speedily and permanently cured. Reference was made to a pyloric spasm produced by a small ulcer at

the pylorus, by which symptoms resembling mechanical interference are produced. While the author considers that pyroplasty is fairly effective in this form of the disease, he states that it does not compare with the benefits derived from gastroenterostomy, although the division of the pyloric sphincter stops the spasms and the enlargement of the opening exerts a healing influence on the ulcer. Gastroenterostomy on the small stomach affected by ulcer does not, as a rule, give immediate relief, although the ulcer will eventually heal, but the results are not as good as in the other class of cases. The author then referred to the use of the Murphy button and the union of the jejunum to the anterior wall of the stomach as near the greater curvature as possible, which operation he considers equally as good as the posterior and easier of performance. He stated that three-fourths of the cases which had come under his observation had been operated on for the relief of non-malignant disease, largely pyloric obstruction, the result of healed ulcer, and that there had been but one death in over forty cases. In malignant cases the death rate was over twenty-five per cent.

Dr. W. G. Macdonald, of Albany, New York, reported two cases of posterior gastroenterostomy for the relief of chronic ulcer of the stomach. One case, which had existed for eight years, did very well for ten months, when distinct symptoms presented themselves of a well-developed tumor in the region of the pylorus, the patient dying shortly afterward of carcinoma of the stomach. The second case was very similar, except that the improvement following the operation lasted for a somewhat longer time. In his opinion the ideal operation for these conditions is extirpation of the ulcerated surface, even though it involves resection of the stomach or partial gastrectomy.

Dr. William L. Rodman, of Philadelphia, called attention to the fact that malignant degeneration frequently takes place on the site of an old benign ulcer, and also that the great majority of gastric ulcers is situated posteriorly, and not anteriorly. In his opinion adhesions play a very important part in these conditions, but he felt that, if the ulcer is anterior and free from adhesions the operation should be done, while, if it is posterior, it is out of the question.

Dr. Robson did not close the discussion, except to thank the gentlemen present for the interest they had taken in his paper.

Dr. R. Matas, of New Orleans, read a paper on "Artificial Respiration," and demonstrated a new apparatus therefor.

Third Day, Morning Session.

"The Treatment of Arterio-Venous Aneurysm of the Subclavian Vessels" was the title of a paper read by Dr. R. Matas, of New Orleans, who reported a case of perforation of the right subclavian artery and vein, through the scalenus anticus, by a bullet; the patient being a young man aged 24. The bullet also injured the brachial plexus and caused paralysis of the corresponding upper extremity. Ten days subsequent to the injury the operation was performed. An osteoplastic resection of the clavicle with disarticulation at the sterno-clavicular joint was made under local infiltration anesthesia with Eucain B. and a temporary traction loop of silk was applied under the first portion of the anomalous subclavian artery, the innominate being absent. The vein was provisionally compressed above and below the anastomotic orifice. Profuse hemorrhage occurred when the vein was detached from the artery in spite of the fact that complete control of the subclavian at its orifice had been obtained, the bleeding being stopped by the application of double ligatures above and below the perforation of the artery. Indirectly the bleeding had its source in the vertebral and internal mammary. The artery between the ligatures was divided, the orifice in the vein closed by a lateral suture and venous circulation re-established. An undeformed bullet, 38 calibre, was extracted and shock followed, the patient being restored by saline infusion. Primary healing of the operative wound and recovery with partial loss of the hand and forearm from mortification caused arterial ischemia and insufficient collateral circulation followed.

In a review of the literature the author stated that but 15 cases had been recorded since 1829, when the first was published by Leary, and in only 4 of these has operative procedure been resorted to. In concluding the indications for intervention, the prognosis and the details of the operative technique were considered.

This paper was discussed by Dr. Arthur Dean Bevan, of Chicago. W. S. Halsted, of Baltimore, Theodore A. McGraw, of Detroit, and closed by Dr. Matas.

Operative intervention in tumors of the liver with a report of cases, was the title of a paper by Dr. W. G. Macdonald, of Albany, N. Y., which was not read.

Dr. E. H. Bradford, of Boston, presented a paper on Subtrochanteric Osteotomy, which was read by title.

Dr. A. Vander Veer, of Albany, N. Y., read a paper on Phlebitis following abdominal operations in which he stated that acute perforative appendicitis is more prevalent in August and September, because of the diet in which young people indulge, and in December and January because of exercise and exposure, but it was only of late that he had had any symptoms of phlebitis, four cases having occurred in the past two years. He referred briefly to the history of these cases and felt that possibly tight bandaging might have had something to do with at least two of them.

There was never any delay in the union of the wound, and attention was called to the strange coincidence that the cases occurred very near each other and immediately after beginning work in a new Hospital. He advised careful watching of the bladder and the bowels in these cases and stated that in addition the treatment should consist of rest, elevation of the limb, anodynes to control pain with hypnotics to afford sleep and diffusible stimulants and tonics, as may be required.

This paper was discussed by Dr. George R. Fowler, of Brooklyn, and Dr. William J. Mayo, of Rochester, Minnesota, as well as by Dr. Lange, of New York, Dr. Vander Veer closing.

William J. Mayo, A. M., M. D., of Rochester, Minn., read a paper entitled, "An Operation for the Radical Cure of Umbilical Hernia," stating that patients suffering from umbilical hernia are usually obese with attenuated muscles. It is sometimes wise to reduce the weight before operation. The neck of the protrusion should be exposed early and its omental contents ligated off at this point saving time. The writer has made the following method nineteen times. The steps of the operation are as follows:

A traverse elliptical incision is made at the base of the hernial protrusion to and through the peritoneum. Traction upon the hernia exposes its contents at the point of entrance. Return of intestine, if present, and ligation of extruded omentum. Exposure of the aponeurosis above and below the margin of the incision. The lower flap of aponeurosis and peritoneum is slid upward three quarters of an inch into a pocket previously formed, between the upper margins of aponeurosis and the peritoneum. Retention by two rows of buried sutures. The sliding can be made from side to side in the same manner as was so performed in ten of the nineteen reported cases. If the ring is very large the overlapping from above downward is easier of performance.

Dr. A. J. Ochsner, of Chicago, opened the discussion, in which Dr. F. H. Gerrish, of Portland, Maine; Dr. DeForest Willard, of Philadelphia, Dr. A. J. McCosh and Dr. W. B. Coley, of New York, and Dr. J. Collins Warren, of Boston, participated, Dr. Mayo closing.

Dr. James E. Moore, of Minneapolis, read a paper entitled "The Prevention and Cure of Post-operative Hernia," in which he stated that ventral hernia is rare among good operators except after operation for acute appendicitis. He believed that the same rules should govern the treatment of post-operative hernia that governs the treatment of other hernia. Operation, in his opinion, is the only treatment to be considered, and should be done early, the prognosis being almost always good.

This paper was discussed by Dr. Arthur D. Bevan, of Chicago, and closed by Dr. Moore.

Afternoon Session.

Dr. S. H. Weeks, of Portland, read a paper on "Fractures and Dislocations of the Spine," which was discussed by Dr. John C. Munro, of Boston; Dr. S. J. Mixter, of Boston, and Dr. R. H. Harte, of Philadelphia. The author did not close.

Dr. W. B. Coley, of New York, read a paper on the "Radical Cure of Inguinal and Femoral Hernia," with a report of 800 cases operated upon from 1881 to 1901, which was discussed by Dr. J. Collins Warren, of Boston, and Dr. W. S. Halsted, of Baltimore, Dr. Coley closing.

A paper on The Use of Silver Wire and Electricity in the Treatment of Aneurysms, with report of cases was read by Dr. Leonard Freeman, of Denver, and discussed by Dr. J. M. T. Finney, of Baltimore; Dr. DeForest Willard, of Philadelphia, and Dr. R. Matas, of New Orleans; Dr. Freeman closing.

A paper on Movable Kidney: Its Cause and Treatment, was read by Dr. M. L. Harris, of Chicago, but was not discussed.

Dr. S. J. Mixter, of Boston, read the following papers:—

(1) Two cases of abdominal contusion; (1) Fracture of Spleen—Splenectomy—Recovery. (2) Fracture of Kidney—Nephrectomy—Recovery.

2.) Nephrolithotomy on both Kidneys.

Dr. Charles A. Powers, of Denver, presented with photographs a paper on *Giant Sacrococcygeal Tumors*. The subject of especial observation was a male child first seen at three months of age, at which time there was found an enormous growth occupying the sacrococcygeal region, extending laterally to the buttocks and forward in front of the anus. It was irregularly ball shaped, and in size as large as the head of a child of six years. Below and in front the growth was cystic; above and laterally it was firm, and in places nodular. The skin over the tumor was of a bluish-red over the cystic parts, normal above and at the sides. Deep palpation showed no gap in the bony structures. There was nothing abnormal about the rectum. The tumor was moved by the gluteal muscles, but the tension of the mass was not changed when the child cried. There was no paralysis nor anesthesia of the lower extremities.

No operation was advised and the growth underwent spontaneous contraction. The skin did not ulcerate, the contents of the cystic portion were absorbed, and when the child was three years and nine months old the tumor had shrunk to the size of a man's fist, and was well flattened out over the sacrococcygeal region. The boy is as strong and healthy as other lads of his age; lies on his back and sits like other children; except for its mere presence, the tumor gives no symptoms.

While this growth lacks pathological confirmation, it is assumed that it is a teratoma or embryoid tumor having a double germinal substratum. A certain number of such tumors have been observed by German and French writers and when pathologically examined have been found to contain the greatest diversity of tissue. Cysts lined with various forms of epithelium, intestinal remnants, masses of gliomatous tissue, smooth and striped muscle fibre, bone, cartilage, etc.

The question of operation must be decided by the surgeon in the individual case. In general it is recommended that operation be deferred until the child reaches such age as to enable it to successfully withstand operative procedure. The author's case shows that spontaneous contraction may occur.

"Resection of the Chest Wall For a Large Sarcoma. Successful Use of the Anti-streptococcic Serum."

The above was the title of a paper read by Dr. W. W. Keen, of Philadelphia. The author referred very fully to the details of the operation, together with the condition of the patient before and after. In concluding his remarks he called particular attention to:

(1) The method of separating the tumor from the chest wall so as to determine more exactly the limits of the disease and lessen the size of the opening to be made in the chest. (2) The division of the ribs anteriorly and posteriorly prior to opening the pleural cavity; this diminished very much the period of danger in the collapse of the lung. (3) The use of Fetl's apparatus, which was not satisfactory in this case and for which he prefers to substitute the apparatus of Dr. Bloom, of New Orleans, which he then showed to the association, or the apparatus of Matas which was then demonstrated by its inventor. (4) The suture of the lung to the chest wall, which was followed by no untoward surgical result. It diminished very greatly the amount of post-operative pneumo-thorax and in fact one might almost say abolished it. (5) The use of the anti-streptococcic serum and as to whether it was the cause of the fall in temperature or only a coincident, the results seeming to be so striking. (6) The examination of the blood which was of great value as showing the reason for the continued high temperature and led to what the author believes to have been the proper treatment for the condition.

In the opinion of the doctor it is too early to determine what will be the future of the patient but up to the present time, a period of nearly seven months, the results have been entirely satisfactory.

Dr. R. Matas, of New Orleans, exhibited an apparatus for local infiltration anesthesia.

Drs. Hearn and Roe reported and exhibited a case of a large abscess of the lung, of 22 years duration, probably the result of local gangrene following pneumonia. (Patient male, age 26).

Pneumotomy was performed and the abscess drained for two years with much improvement in general health; marked lessening of the previous horribly offensive odor, but without any healing or reduction in the size of the cavity.

They again operated and excised a portion of the abscess wall, stitching the margins of the remainder to the skin surface, thus converting it into an open cavity, with relief from the annoyance of wearing a drainage tube and of cleansing the cavity and with practically entire cessation of odor.

Although about six months have elapsed, the cavity remains unchanged and there is evidence of secondary bronchiectasis for which they assign two probable causes; i. e. cough and cirrhosis of lung tissue. To obliterate the original cavity and to relieve the bronchiectasis or cure it, they propose to remove the greater portion of the lower ribs, with their periosteum, in this way allowing the chest wall to collapse upon the lung.

The case demonstrates the greatest difficulty of definitely localizing an old abscess of the lung with tough, elastic walls which collapse when empty, by either of the two methods, namely: aspiration and palpation; the value of the X-ray; the practicability of giving ether as a general anesthetic; the absence of any embarrassment of respiration by the entrance of air through drainage tubes introduced into the cavity, although they freely communicate with the bronchus; the ease with which the cavity could be flooded with different fluids or solutions, although they entered the bronchus and caused expulsive paroxysms of coughing; the advantages gained by draining the cavity by tubes or by the open method, but without any evident obliteration of the abscess cavity.

A portion of the ninth rib, in this case, was resected, the third time, having been twice performed.

The presence of pleural adhesions rendered the operations in this case free from the dangers of pneumothorax and, although a localized pyothorax occurred subsequent to one of the operations, it did not delay convalescence.

Meeting place next year, Albany, New York. Date, May. President, Dr. DeForest Willard, Phila.

GREAT BRITAIN.

Gold Medal Awarded. The gold medal presented to the Royal College of Surgeons, Edinburgh, by Colonel Lorimer Bathgate, in memory of his father, W. M. Bathgate, F. R. C. S. Ed., as a prize in *Materia Medica*, has been awarded to Mr. R. B. Johnston, of Edinburgh.

Lieutenant-Colonel Babbie, V. C., C. M. G., has been temporarily appointed Assistant Director of the Army Medical Service.

Appointment. Dr. S. West has been appointed Joint Lecturer on Medicine at St. Bartholomew's Hospital, in the place of Sir Dyce Duckworth.

CONTINENTAL EUROPE.

Dr. Laveran, the discoverer of the plasmodium of Malaria, has just been elected a member of the French Academy of Sciences, to fill the chair made vacant by the death of Professor Potain.

Appointment. Dr. J. J. Déjerine, the eminent neurologist, has just been appointed Professor of the History of Medicine and Surgery in the Medical Faculty of the University of Paris. He was born in Geneva in 1849, and graduated in medicine in Paris in 1879.

Dr. Troisier, physician to the Beaujon Hospital in Paris, has been nominated to fill the chair of the late Professor Potain in the Academy of Medicine of Paris.

Appointment. Dr. Ollive, Professor of Hygiene and Medical Jurisprudence at Nantes has been appointed Professor of Clinical Medicine.

Dr. Kirmission has just been appointed Professor of Surgery of Children in the Medical School of Paris.

No Passports to Lepers. Germany, Russia, and Roumania have decided, that in the future no passports be issued to lepers, and have formed an agreement to that effect.

The Soemmering prize has been awarded by the Senckenburger Natural History Society, of Frankfurt, to Prof. Franz Nissl, of the University of Heidelberg, for his discoveries in the finer structure of the nerve cell.

Baths on the Trains. Russia proposes to have baths and douches on trains running long distances. An innovation well worth considering.

The Prevalence of Tuberculosis in Russia. Between 1892 and 1894, inclusive, there were 1,475 deaths from cholera, while the number of deaths from tuberculosis during the same period reached 10,650. The annual mortality from tuberculosis all over Russia is between 360 and 450 thousand, while the number of persons affected with the disease is estimated at 2-2½ millions. The disease is concentrated principally in large cities, such as Moscow and St. Petersburg.

Tuberculosis Barred him from the Position. In the government of Poltava a physician applied for the position of district physician. When the application came up for consideration a member of the city council raised objection on the ground that the applicant is affected with tuberculosis and is liable to infect the patients. The physician entered suit for libel and secured conviction of the councilman, the latter having been sentenced to two week's imprisonment. A reconciliation however was brought about, and the sentence commuted.

A Useful Amusement for Hospital Inmates. The hospital of Alafusoff was recently fitted up with an expensive magic lantern for the amusement as well as instruction of the patients. Once a week pictures are thrown on the screen and descriptive lectures delivered by the hospital physician.

Engineers Better Paid Than Physicians. It appears that in Russia an engineer commands a salary of four to five thousand roubles, while a physician in the employ of the city is satisfied with 750, and even at that he is glad to get the appointment.

The Plague in Kirgiz.—The number of plague-stricken persons in Tubekai-Tubek and Merek up to the 24th of January reached 136. Of these 134 died. The place is now claimed to be free from the disease.

A Premium for the Best Paper on Rabies.—The Moscow Society of Hunters placed in the hands of the Physico-medical Society 1000 roubles (500 dollars) as a price for the best paper on the subject "Canine Rabies, its Cause, Prevention and Treatment." The paper is to be written in Russian and sent not later than November 1, 1901.

Corporal Punishment Condemned.—The medical society of Omsk resolved to petition the authorities to abolish corporal punishment in Russia.

Atypical Forms of Typhoid Fever.—Ia. M. Brainin (*Russki Medicinski Vestnik*, Vol. 111, No. 7), in speaking of the atypical forms of typhoid, quotes the late Prof. Botkin as saying that typhoid fever may last only several hours. His pupil Borodulin found in a large number of cases rose spots in 84%, diarrhea in 68%, sweating in 81%, bronchitis in 68% typhoid state in 62%, and enlarged spleen in 64%. The author observed an epidemic of typhoid fever affecting about 300 persons, with a mortality of 10%. The most prominent symptoms were: a dull headache during the entire course of the disease, a typhoid state, continuous and occasionally remittent fever and a slight enlargement of the spleen. No abdominal or any other symptoms characteristic of typhoid were observed. The disease terminated by crisis in 2-3 weeks. Death in the fatal cases occurred on the 2-3 week period. (A. R.)

1.—Smyly remarks that the origin of the lower segment of the uterus is still uncertain, and four different theories are held in regard to it: (1) That it develops during pregnancy; (a) From the lowest part of the corpus uteri (Schroeder, Hofmeier, C. Ruge); (b) From the upper part of the cervix (Bandl, Kustner, Kaltenbach). (2) That it forms only during labor (a) from the cervix uteri (Zweifel); (b) both from the body and the cervix (v. Herff). In a third stage the lower segment and cervix form a continuous thin-wall collapsible tube which affords no support to the upper segment, which contains the placenta.

The lower segment of the uterus is the part most frequently involved in rupture. As to the contraction ring as a cause of dystocia, Rossa describes three varieties of constriction. (1) The contraction occurring during a few pains, disappearing in the intervals and easily overcome by the advance of the fetus. (2) A permanent stricture associated with tetanus uteri. (3) A constriction which occurs early continues during the intervals but increases during the pains and is associated with a diminution of the entire contractile portion of the uterus, and therefore only met with at an advanced stage of labor. As regards the treatment Budim advises mechanical dilatation, but Veit believes that patience and narcotics will suffice. [W. A. N. D.]

2.—Spencer presents a paper on the dangers and diagnosis of breech presentation, in which he states that Hegar's statistics show 35% of still born children, with an additional 5% dying on the first day. His maternal mortality was also 1% in breech cases. Ramsbotham, whose statistics deal only with labors at term, give an infantile mortality of 18.7%, and Hecker of 22%. Pinard had a mortality of 19.5%. Spencer gives a mortality of male children of 30.82% and of female children of 18.3%. The causes of death in these presentations is prolapse of the cord, pressure upon that structure, attempts at respiration before birth, and injury of the body from its being subjected to the brunt of the labor resulting in visceral injuries. Hemorrhages into the muscles are very frequent in breech presentation, especially when traction is employed to deliver. Another injury which not infrequently follows the presentation is the so-called obstetrical palsy from damage to the brachial plexus during violent traction on the shoulders. Fractures of the bone especially those of the upper limb, and even of the pelvic bones may be noted. Spencer favors treatment of this complication by external version toward the end of pregnancy, whereby the mortality may be reduced to as low as 12% or 13%. Contraindications to the performance of this operation are twin labor, considerable flattening of the pelvis, a dead fetus, a malformed uterus, and placenta prævia. [W. A. N. D.]

3.—Sheild reports 4 cases of cystic affection of the breast, which closely simulated carcinoma of that organ. He states that these deeply seated cysts vary in size and sometimes spontaneously disappear. Two important points in the diagnosis of cysts is variation in size and variation in local tenderness. The tenser the cyst the more is the sensation of actual hardness simulated. A sensation of elasticity is diagnostic of a cyst. Nothing is more deceptive than to argue of the nature of a breast-tumor from the condition of the axillary glands. Cancerous infection may be present and yet it may be impossible to feel the glands from surrounding fat or deep situations. On the other hand in those women suffering from cysts the axillary glands may easily be felt and they may be enlarged if the part has been much handled or painted with iodine. With regard to the treatment of simple cyst after exploratory incision the sac may be dissected out or it may be emptied with carbolic acid or

iodine or packed with gauze. The exploring trocar and canula in these cases of doubtful swelling are of great value. [W. A. N. D.]

4.—Nason has made an inquiry into the influence of locality on the prevalence of malignant disease, and has analyzed more than 5,000 cases from death from the various forms of cancer. Of these cases 1837 were males, and 3,013 were females; in 145 the sex was not stated. The great preponderance of female cases is due to the very great frequency with which cancer attacks the uterus and female breast; of all the female cases, in 40% it is one of these two organs which is effected. Many of what may be called the predisposing causes of cancer come much more frequently into operation in the male than in the female, as, for instance, trauma and syphilis. Cancer is far more common in the male than in the female in the following situations: tongue, bladder, esophagus, jaws, face, mouth, limbs, lips and stomach. A large proportion of deaths from cancer in the male are due to cancer in the stomach and the pylorus. About three-fourths of all the cancer occurring in the male occur in the alimentary tract. [W. A. N. D.]

5.—Walker has seen four cases of erythema multiforme in patients who had been recently vaccinated, all of which showed features that made it seem certain that the vaccination was causally related to the eruption. One of the patients was a nurse whose hands presented a typical picture of erythema iris. The legs were also affected and the eruption spread up the arm beyond the usual limitation of erythema iris. The vaccination scabs were still moist and were surrounded by a raised erythematous patch of the same character as the eruption elsewhere. The other cases were not so perfect in the mimicry of the real disease. All of the patients had been vaccinated with glycerinated lymph and in all of them the early course of the vaccination was uneventful. [J. M. S.]

LANCET.

May 18, 1901.

2. A Clinical Lecture on Cases Illustrating the Surgery of the Thyroid Gland. HENRY BETHAM ROBINSON.
3. A Paryngeal Pouch of Large Size Removed by Operation. RICKMAN J. GODLEE and T. R. H. BUCKNALL.
4. Flies and the Science of Scavenging. G. V. POORE.
5. A Case of Symmetrical Retinal Detachment occurring during Labor and Associated with Albuminuria resulting in Complete Recovery. REGINALD G. HANN and R. LAWFOED KNAGGS.
6. Is the Murmur of Mitral Stenosis Systolic or Presystolic in Rhythm? HUGH WALSHAM.
7. Opothorapy in Gynecology. JOHN PHILLIPS.
8. Some Questions with Regard to Acute Middle-Ear Inflammation. P. McBRIDE.
9. A Simple Form of Electrical Light and Heat, with Eight Cases of Osteo-arthritis treated by it. F. C. EVE.

2.—Henry Betham Robinson reports a number of cases illustrating the surgery of the thyroid gland. Case 1 is a parenchymatous goitre which was reduced by the administration of thyroid extract. Case 2 is a parenchymatous goitre in which the pyramidal lobe was so enlarged as to produce serious pressure upon the trachea and greatly embarrass respiration. The isthmus of the gland was removed without ligation laterally. The patient became asphyxiated during the operation and tracheotomy was necessary. The patient suffered at first from some thyroidism but made a complete recovery. Case 3 closely resembles case 2 in symptoms and treatment; here, however, the thyroidism was much more marked. The last four cases represent cystic adenomata of the thyroid gland, each of which was treated successfully by operation. The author remarks that the removal by the knife of these cystic growths is far more satisfactory than other methods of treatment such as tapping and injection. [J. H. G.]

3.—T. R. H. Bucknall reports an interesting case of a large pharyngeal pouch removed by operation. The sac had its attachment at the top of the larynx, the movements of which it followed during deglutition. The patient was 31 years of age and had experienced symptoms for ten years. During the past three years he had had repeated attacks of difficult and painful deglutition until finally it became impossible to swallow anything but liquids. At the end of an attack the tumor in the neck disappeared, sometimes gradually and sometimes suddenly. Expectoration of a quantity of phlegm was frequent. The swelling on admission was very extensive, reaching from the middle line in front to the posterior border of the sterno-mastoid behind, and extending upwards as far as the angle of the jaw, and downwards as far as the clavicle. The percussion note over this tumor was tympanitic. The patient could slightly inflate the tumor by holding his breath and blowing. The tumor was dissected out with considerable difficulty and was found to have a narrow pedicle which passed through the thyro-hyoid membrane, but no patulous opening which led into the pharynx could be discovered with the probe. The internal opening of these abnormal tracts or pouches is always found in the pharynx and not, as was formerly stated, in the larynx. A frequent site of the internal opening is on the side of the pharynx close to the margin of the tonsil. It is rare for food to pass into the cyst as frequently happens in cases of true esophageal pouches. These cysts and fistulae are always of congenital origin. [J. H. G.]

4.—Poor writes on flies and the science of scavenging. The author remarks that in a recent debate of the clinical society of London on enteric fever in South Africa, the general consensus of opinion was that flies may convey infection. He informs up that the female fly lays about 120 eggs and that the developmental cycle from egg to fly requires less than three weeks. At this rate the female fly may have some 25,000,000 descendants in the course of a hot summer. The plague of flies can be lessened by the proper removal of organic refuse matter, so that it cannot serve for feeding these insects. He recommends immediate collection of all organic refuse and burying this matter in the earth. He believes that his method is preferable to chemical disinfection or burning. [F. J. K.]

5.—Reginald G. Hann and R. Lawford Knaggs report a case of symmetrical retinal detachment occurring during labor and associated with albuminuria resulting in complete recovery. The affection occurred in a woman aged 21 years whose personal history was negative up to the time of her first confinement, excepting an attack of scarlet fever in childhood. When first seen after having been in labor 24 hours, there was edema of the face, hands, feet and legs which was reported to have been present for about three weeks. As far as could be ascertained the blindness was sudden in onset. Labor was terminated with forceps. The following day she remained in a semi-comatose condition and for 30 hours from delivery she passed no urine. She regained consciousness and passed a small quantity of urine containing much albumin. Ophthalmoscopic examination under atropin showed large and distinct attachment occupying the lower third of each eyeball. The edges of the discs were well defined but surrounded by an edematous pallor. About a month later the detachments of the retinae were no longer visible except a doubtful area close to the ora serrata in the lower part of the right eye-ball. There was slight tortuosity of some of the vessels. There was an irregular distribution of pigment granules, spots and patches, and the latter in some places, especially in the right macular region were confluent. A subsequent examination failed to reveal any remnants of the detachment in the right eye. The fields still showed limitations in the upper portions. [M. R. D.]

6.—Walsham has made a routine examination of all his cases of mitral stenosis with the X-Rays in order to determine whether the murmur is systolic or presystolic in rhythm. The author concludes that after an examination

of a number of cases of pure mitral stenosis, he is convinced that both the thrill and the murmur are presystolic in rhythm. [F. J. K.]

7.—Phillips in speaking of opotherapy remarks that ample clinical evidence shows that certain nutritional disorders associated with pelvic disturbance are undoubtedly benefitted by the administration of thyroid extract. It is certainly of value in amenorrhea accompanying extreme obesity and as a complication of myxedema. According to some authorities it is beneficial in the hemorrhages of fibroid tumors of the uterus. As regards the ovarion extract the methods of administration appear to be three: 1. That followed by Knauer, who grafted the fresh gland into the peritoneum or under the skin; 2. Brown-Séquard's method by subcutaneous injection of the organic extracts; 3. the method recommended by Horwitz and others and now in general use, namely, administering the extract by the mouth or the rectum, either in a natural state, in the form of ovarine tabloids, or as a glycerin extract. Jayle has observed zona, and Schuster general urticaria, after prolonged ingestion of ovarian extract. Julien finds the drug of great value in post-operative menopauseal symptoms, in amenorrhea, dysmenorrhea, anemia, chlorosis, and osteomalacia. The administration of mammary abstract is surrounded by greater uncertainty. It is best given in the raw state, cow's udder being cut into thin slices and made into a salad. This method has been frequently prescribed and carried out by Freudenberg. [W. A. N. D.]

8.—P. McBride reports a case of a man aged 48 years whom he treated for some time for a suppurating middle ear. The usual treatment and several incisions of the drum failed to relieve the condition and it was subsequently discovered that the patient had an empyema of the antrum of Highmore. The empyema was on the right side and the ear affection on the left. The antrum was thoroughly opened and drained and when it had healed the ear condition promptly subsided. [J. H. G.]

8.—Eve recommends an apparatus consisting of three 32-candle power lamps surrounded by a wire cage, in order to prevent contact with the skin of a patient, and arranged upon an aluminum base, for heating a part or the whole of the body. He maintains that this apparatus possesses many advantages over the more elaborate contrivances now in use. When heating a limb the apparatus and a thermometer are placed under several blankets thrown over a cradle. The limb is protected by a single layer of lint to prevent scorching a particularly tender skin. The temperature may be raised from 200° F. to 250° F. in from 15 to 30 minutes. Eve has treated 8 cases of osteoarthritis by this method with favorable results. [J. H. G.]

6. A Few Observations from the Lorenz Orthopedic Clinic. LEONARD W. ELY.
7. A Case of Membranous Angina, due to Streptococci, followed by Paralysis of the Soft Palate. MOSES KESCHNER.

1.—Augustin H. Goelet discusses the diagnosis and surgical treatment of prolapse of the kidney. True floating kidney is very rare and is always congenital; prolapsed kidney is very common and always acquired. He con-

cludes: (1) That prolapsed kidney is more frequent than is generally supposed. (2) That it is often not suspected because it does not always give rise to symptoms directly referable to the kidney. (3) That frequently it is not discovered because, by the usual methods of examination, only an expert can detect it, unless the kidney is much enlarged or the subject is thin and the abdominal walls relaxed. (4) That palliative measures, such as abdominal supports, are of no avail and therefore useless and unwise if the degree of prolapse is sufficient to produce symptoms. (5) That fixation of the kidney by suture to the muscles of the back in its normal position is the correct method of treatment. The operation is simple, devoid of risk and successful when properly executed and when the patient is given careful preparation to avoid vomiting and retching with consequent straining after the operation and if proper attention is given during convalescence to avoid strain upon the kidney. Prolapsed kidney the author has found in 1 out of every 4 or 5 gynecological cases and about one-half of these suffer sufficiently to require operation. The various supports recommended for this condition are productive of little good excepting to perhaps limit the prolapse. The various supposed causes of prolapse of the kidney are referred to but the author thinks none of them perfectly satisfactory. The symptoms of prolapse are as follows: (1) Chronic digestive disturbances, manifested chiefly by intestinal distention and irritability of the stomach. (2) Nervousness, restlessness and insomnia. (3) Unusual fatigue after walking or standing. (4) Palpitation of the heart, vertigo and syncope. (5) Pain over the pit of the stomach and a little to the left over the region of heart. (6) Dragging pains in the loin extending down the thigh and aggravated by standing or walking. (7) Inability to rest comfortably on the opposite side from the prolapsed kidney. (8) Irritability of the bladder, aggravated by standing or walking. (9) Jaundice. (10) Pain over the region of the appendix, resembling chronic appendicitis. (11) Pain referred to the ovarian region on the same side. (12) Acute attacks of pain resembling renal colic, which come on suddenly and subside quickly. Frequently cases are referred to the gynecologist for supposed pelvic disease when the real trouble is a prolapsed kidney. In all gynecological cases Goelet urges that an examination of the kidneys be made and made repeatedly, as under unfavorable conditions the diagnosis of prolapse of the kidney is not easily made. His own method of examination, which he finds very satisfactory, is as follows: The patient is directed to stand with her back to the wall or a table, perpendicular to the floor, her body inclined a little forward, so as to relax the abdominal muscles. The examiner sits in front of her a little to the right and grasps with his left hand the right loin, his fingers behind and his thumb in front, just below the border of the ribs. The patient is now directed to take several deep inspirations and to expire to the extreme limit; at the end of the second or third inspiration he depresses the abdominal wall with his thumb so as to diminish the distance between the thumb and the fingers behind, in this manner approximating the anterior and posterior walls above the kidney if it is prolapsed. With his other hand, the right abdominal region is depressed by pushing the tips of the fingers inward and engaging the kidney if prolapsed between the tips of the fingers of his right hand and the thumb of the left which depresses the abdomen just beneath the ribs. In this manner the kidney, if prolapsed, may be outlined, and firm pressure upon it will cause it to glide under the thumb and up into position. When the degree of prolapse is insufficient to demand operation, he says that the symptoms may be relieved by a properly adjusted bandage with a pad over the kidney but that no cure can result from this treatment. Operation is indicated where symptoms cause positive discomfort or interfere with the health of the patient. Where the patient suffers from attacks of acute pain denoting obstruction of the ureter operation is imperative. The author uses silk-worm gut sutures and carries out his fixation in the following way: The needle carrying the suture is first inserted superficially on the lateral surface of the exposed kidney from above downward in a direction somewhat oblique to its long axis. Then it is inserted deeply through the kidney structure transversely and again superficially on the opposite lateral surface from below upward. The free ends of this suture are passed through the fatty capsule of the kidney and muscles and skin at the upper angle of the wound so that when they are drawn upon and tied the

kidney is drawn up into position under the ribs. This method of inserting the suture lessens the strain upon the central insertion through the kidney structure. To obviate the cutting of these sutures into the skin, he ties them over a strip of several layers of gauze placed lengthwise over the wound, but before they are tied he inserts a roll of sterile gauze down into the wound and along the border of the kidney, and brings it out at the lower angle of the wound. The object of this is to secure drainage and to excite, by contact with the kidney, a plastic inflammation which aids in its fixation. [T. H. G.]

2.—LeGrand N. Denslow presents a carefully prepared paper upon the climate of Long Island. In his summary he states that the configuration of the land is good, the air is both from the ocean and the shore, with great mobility, due to the constant daily ocean winds. The water from the wells or springs is of the purest, and the humidity is not excessive. He believes that it compares favorably with some of the most celebrated coast climates. [T. L. C.]

3.—George W. Hopkins reports the beneficial employment of superheated air in the therapeutics of chronic catarrhal otitis media. The treatment consists in thoroughly cleansing the ear with alcohol for several days. Narrow strips of dry gauze are then packed into the ear and a large pad of dry gauze placed over the ear. The ear is then covered with the canvas-sleeve hot-air conductor and a current of air sent into the canal at a temperature which gradually attains 400 degrees F. The temperature is easily borne, but a severe headache usually follows treatment. This is speedily relieved by a dose of codein. The Eustachean tube is always inflated with a warm, stimulating vapor from a nebulizer after the treatment, and this is concluded with vibratory massage with the nebulizer. The writer regards arteriosclerosis, serous effusion into the tympanum and perforations of the tympanum as contraindications of this treatment. [T. L. C.]

7.—M. Keschner reports a case of membranous angina due to streptococci followed by paralysis of the soft palate. The patient presented on admission a thick, yellowish-grey tenacious membrane covering the tonsils, uvula, and anterior and posterior pillars of the fauces, with signs of profound systemic infection. The appearances resembled diphtheria, but bacteriological examination showed only the presence of streptococci. On the 11th day, paralysis of the soft palate was noted. There was also a distinct loss of sensibility. The patient was discharged in two weeks with only slight improvement of the paralysis. [T. L. C.]

5. A Case of Sarcoma in the Muscles of the Right Shoulder, with Perforation into the Spinal Canal, and Paraplegia. LEONARD WEBER.

2.—Thienhaus concludes his article with the following: (1) As it is almost a law now-a-days that in all gynecological abdominal operations, especially in cases of inflammation of only the right annexa, the appendix demands strict observation and removal, so the same rule must be followed in operations for hernia, and when we take into consideration that in all cases of appendicular hernia the appendix was found in a state of chronic folliculitis, the author probably does not go too far when he says that in every case of hernia in which we find the appendix as an inmate it must be removed according to the old rule in *prophylaxi est salus aegroti*. (2) Where appendicular inflammation is present in a hernial sac, operative procedure has to be advised immediately, and in case of incarcerations under such conditions every palliative method, such as ether refrigeration, or attempts at taxis, are entirely objectionable procedures. (3) In cases of appendicular abscess in a hernial sac or gangrene of the appendix, resection and free drainage without reduction is the appropriate treatment, and if

incarceration exists, this has to be relieved and the peritoneal cavity walled off carefully by iodoform gauze. The radical cure of the hernia, of course, has to be delayed, under these conditions, till the signs of inflammation have subsided. [T. M. T.]

3.—Smith thinks that not enough attention is given to the disease of the intima and the fibrous tunic when considering the various coats of the arteries. The effect of calcification in destroying the elasticity of the vessels and making their walls rigid is what we think of first in this connection. The mechanical obstacle which this condition necessarily presents to the forward movement of the blood is of the first importance and this is entranced when fibrosis of the outer coat is added. But in the latter case the effect goes beyond the mere impairment of elasticity. The delicate fibers of the vasomotor system distributed to the muscular coat are stretched and compressed by the greatly thickened and condensed outer coat through which they pass. [T. M. T.]

MEDICAL NEWS.

June 1, 1901. (Vol. LXXVIII, No. 22).

1. Some Factors Relating to the Etiology of Prostatic Enlargement. J. BENTLEY SQUIER.
2. Gastric Ulcer and Muco-Membraneous Colitis at the Paris Congress. JAMES J. WALSH.
3. Streptococcus Bronchitis in Influenza. F. FORCHHEIMER.
4. Fourth-of-July Tetanus. H. GIDEON WELLS.
5. The Use of Methylene-Blue Injections in Pleurisy with Effusion. CHARLES H. LEWIS.
6. The Appearance of the Soft Palate a Pathognomonic Symptom of Epidemic Influenza. LOUIS KOLIPINSKI.

2.—Walsh, in his article on Gastric Ulcer and Muco-Membraneous Colitis at the Paris Congress, states that it is a well-known fact that ulcers having the typical characteristics of gastric ulcers have been found in the digestive tract in which there is free acid bathing the surface of the mucous membrane. He says there is little doubt that gastric ulcers are due to self-digestion of the stomach wall, and quotes Rokitsansky and Virchow, who attribute the digestion of the gastric mucous membrane to a disturbance of the circulation in the gastric mucosa and consequent lowering of the resistive power of the tissues. He also names two conditions of the blood which predispose to gastric ulcer: (1) Anemia; (2) Blood disturbance due to an infection somewhere in the body. He divides gastric ulcer also into acute and chronic. Most all gastric ulcers have been classed under the head of chronic, though the acute condition is noticed not infrequently in infectious diseases. [T. M. T.]

3.—Forchheimer gives as his reasons for calling this condition *streptococcus bronchitis* that in all his cases this lower form of life predominated, and in quite a number, notably some of the worst, it was the only bacterium found in the expectoration. In 23 cases studied, the streptococcus was associated with staphylococci alone; in three cases streptococci, staphylococci and the influenza bacillus were associated; in 27 cases the streptococcus alone was found. In the author's cases he noticed that the influenza bacillus disappeared after a short time and was replaced by the streptococcus. He does not think that this is an associated life, (Symbiosis), but considers the condition a secondary infection. [T. M. T.]

6.—Kolipinski is convinced that a diagnosis of influenza can be made by observing the peculiarity of appearance of the velum palati. This appearance was found to precede the initial chill and fever by some days and still persisted when convalescence was apparently ended. There are seen upon the mucous membrane of the soft palate small convex projections of a pearly whiteness or transparency, the size of a grain of sand. The number varies and they are confined to certain parts of the velum or its processes, or else abundantly scattered over the whole of its anterior surface. Best seen at (1) the base of the uvula; (2) the median raphe; (3) the lateral border of the same; (4) the anterior surface of the palatoglossal fold about the upper border of the tonsil. A spatula rubbed over them gives a hard, rough sensation. They are distinguishable in very bright, artificial light, but are best seen in sunlight, direct or diffused. They must not be confounded with small

drops of mucus or saliva often present. Sometimes they are obscured by a tenaceous secretion covering the surface. It is thought that their composition is that of congested or inflamed palatal mucous glands. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

Vol. 43, 1901.

1. The Diagnosis and Surgical Treatment of Renal Tuberculosis. F. THOMAS BROWN.

1.—There are no cases of purely localized unilateral renal tuberculosis which we would entrust to climatic change as the best treatment, as opposed to surgery; and, on the other hand, there are no such cases just recovering from nephrectomy in which we would not seek for the patient 12 months or more of this climatic benefit. Despite the immense amount accomplished by earnest labor in the field of tuberculosis, we have yet to hope that something more specifically curative than the knife, sanitation or the pine woods may soon be hit upon. To secure more satisfactory results from surgical treatment, renal tuberculosis must be detected early. Urinary analysis in general should mean as careful a routine search for tubercle bacilli as is customarily given to the other formed elements of a sediment. Upon this initial evidence the suspicion should be verified and the smegma bacillus excluded by getting the bladder urine through a catheter, then cystoscopic ureteral catheterization may at once be utilized to locate the lesion in the bladder or kidneys. Brown believes that there is no more accurate and simple way to do this in both sexes than with the double-barreled ureter cystoscope, invented by him, each channel of which conveys a flexible sterile catheter to its respective ureter; by this means the urine from both kidneys is collected at the same time, while the same nerve influences and the same physiological conditions pertain. Many patients state that they were never ill until their present trouble began with having to urinate too often. In the majority of cases, however, frequency of urination does not appear until the lower segment of the ureter has either acquired a genuine tuberculous lesion or until marked hyperemia and edema with the accompanying irritable state, have developed about the mouth of the ureter. The principal objective symptoms are: A kidney which is larger and more tender than normal; all grades of pyuria and hematuria; a just appreciable or a very marked diurnal variation in temperature; loss of color and weight; a reaction to tuberculin; and the presence of tubercle bacilli in the urine derived directly from one or both kidneys. In the operative treatment a considerable amount of tuberculous ureter can be left with comparative safety; because, being in a functionless state of repose, this particular focus is amenable to curative systemic processes. In cases presenting tuberculosis vesical lesions where only one kidney is similarly diseased, the author thinks that nephrectomy is indicated in a certain number of individuals as offering the best chances for extension of life and comfort. Short notes of 18 illustrative cases are given. (J. M. S.)

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

June 1st, 1901.

1. Movable Kidney; its Causes and Treatment. M. L. HARRIS.
2. The Appendix Vermiformis and Cecum. A Comparative Study. B. MERRILL RICKETTS.
3. Zoology in the Medical School Curriculum. CHARLES WARDELL STILES.
4. Antipneumococcic Serum Treatment of Pneumonia, with Report of Cases. G. E. TYLER.
5. How to Treat Muscular and Joint Sprains of Railway Employes. HALDOR SNEVE.
6. Diagnosis and Symptomatology in Appendicitis in Children. THOS. H. MANLEY.
7. Is it Possible by Proper Dietetics and Hygiene to Exterminate Tuberculosis? J. E. KINNEY.
8. Variola and Varicella. M. A. AUSTIN.
9. Photographing the Eye-Ground. SHIRLS JACKSON.

1.—M. L. Harris discusses at length the subject of movable kidney, its causes and treatment. The author holds that many of the generally accepted causes of movable kidney are incorrect. He attributes the cause of this condition after the careful study of a large number of cases which he has tabulated, to the particular body form of the individual. This form consists in a marked contraction of the lower end of the middle zone of the body with a diminution in the capacity of this portion of the cavity. This constriction tends to depress the kidney and as it is above the kidney, such acts as coughing, straining, lifting, etc., which tend still more to lessen the circumference of the body at this point crowd the kidney down further and increase its range of motion. These conditions which Harris chooses to call "internal traumata" gradually produce a movable kidney. He thinks that a movable kidney is never the immediate result of a single injury or external trauma. A movable kidney discovered immediately after an accident is oftentimes attributed to the accident, whereas in reality it had probably existed for a long time before. The overlooking of the fact that movable kidney is extremely common in women often leads the practitioner to attribute the condition to a traumatism. When a patient suffers from a movable kidney any traumatism about the trunk is very apt to produce hematuria. In the treatment of the condition the author thinks that the mistake is made too frequently of fixing the kidney too high up, because if this is done the condition which was the original cause of the prolapse of the kidney still pertains and the organ is again apt to become movable. Great stress is laid upon the removal of all perirenal fat and the obliteration of the peritoneal pouch in which the kidney has been moving. The outer edge of the prerenal fascia is then sutured to the lumbar fascia posterior to the line of incision through the walls. [J. H. G.]

2.—B. Merrill Ricketts discusses the comparative anatomy of the appendix vermiformis and cecum. The author says that the appendix is not confined to mammals but is also found in birds, fishes, etc., and discusses its anatomy in each of these as well as in man. [J. H. G.]

3.—Stiles, while admitting that the medical school curriculum is already full to overflowing and that the aim of a medical faculty is not to give a man a general education, but rather to teach him diagnosis and treatment of diseases, firmly advocates the teaching of zoology in medical schools. In his article he sets forth ample evidence to prove this statement and maintains that a course in this branch could be given in from 20 to 30 lectures and at least three laboratory exercises. [F. J. K.]

4.—Tyler discusses the value of antipneumococcic serum in the treatment of pneumonia, and gives a report of a large number of cases. After a careful study of the literature bearing upon this subject and his own cases, he concludes that it is exceedingly doubtful whether antipneumococcic serum has any effect upon the diseased lung. He maintains that this serum will prevent the development of toxic symptoms if large quantities of fresh serum are given before the advent of the pneumococcus into the blood. [F. J. K.]

5.—Haldor Sneve first refers to the treatment and pathology of sprains of joints. He thinks that tearing or rupture of ligaments is extremely rare in sprains. The pathological condition most frequently present is a rupture of the areolar and connective tissue around the joint and a contusion of the lining of the joint. For the treatment of this condition the author recommends the early use of cold applications and massage, to be followed later by compression and the active use of the part such as is obtained by the use of the Gibney adhesive strip dressing. He condemns very strongly the use of the plaster cast in these conditions. "The ambulatory treatment of sprains in conjunction with massage is to-day the best treatment." [J. H. G.]

6.—Thomas H. Manley reviews briefly the history of appendicitis and refers to its frequency in early life. The

youngest patient on record operated on for appendicitis was a child, aged 61 days. Here a large perforation of the tip of the appendix was found. The author thinks that children bear genral septic infection much better than adults. As the cecum is small and quite movable in early life inflammations of this portion of the intestinal canal are much obscured by the inlocation. Two conditions from which appendicitis in children must be differentiated are intussusception and tuberculous peritonitis. The author has not found the examination of the blood to be of great assistance in making a differential diagnosis between appendicitis and other conditions; the most reliable source of information lies in the careful examination of the abdominal wall which, in a child, is very easily accomplished. Abdominal distension and frequent and shallow respiration of a thoracic type are very common in children. The author produces a table representing the mortality of appendicitis in New York city. The author does not think that the premonitory symptoms of appendicitis in children are more subtle and insidious than in adults. The article closes with a discussion of the various types of appendicitis. [J. H. G.]

7.—Kinney maintains that it is possible to **exterminate tuberculosis through proper dietetic and hygienic measures**. At the present time there are two obstacles which hinder advancement in this line, namely, people as a rule who are possessed of a fair degree of health are not ready to make an effort to preserve it, and the individuals who are not affected by the diseases are, as a rule, not willing to accept the proper measures of prevention. [F. J. K.]

8.—Austin discusses **variola and varicella** and gives the important points in the diagnosis of each condition, with particular reference to the epidemic character, the period of incubation, the eruption, and the duration and termination of these diseases. The author maintains that typical cases are to be found only in text-books and rarely in general practice. He gives an account of an epidemic of variola which occurred at Anderson, Indiana. The total number of cases was 149. [F. J. K.]

9.—Jackson gives a description of an instrument used for **photographing the eye-ground**. The instrument is essentially composed of a camera placed behind an illuminating ophthalmoscope. The author remarks that he has met with numerous failures in his attempts at photographing the eye-ground. The best results have been obtained in those cases in which light perception was greatly diminished, or entirely lost. [F. J. K.]

AMERICAN MEDICINE.

Jan. 1st, 1901.

1. A Case of Antrum Infection and Sigmoid Sinus Thrombosis, etc. BAYARD HOLMES.
2. Typhoid Fever and Pharyngeal Diphtheria. MORRIS MANGES.
3. Practical Thoughts on Pulmonary Tuberculosis. HOWARD S. ANDERS.
4. The Recognition of Tabes Dorsalis. THEODORE DILLER.
5. Simplicity in Therapeutics. EDWIN W. PYLE.
6. The Radical Cure of Internal and External Piles by Excision. JOHN A. HAWKINS.
7. Rigidity of the Spine. (Spondylose Rhizomélisque). MAX H. BOCHROCH.
8. Some Notes on a Case of Cerebral Embolism. ANNA M. LITTLEFIELD.

1.—Bayard Holmes reports a case of **antrum infection and sigmoid sinus thrombosis**, without present middle-ear disease; presenting the symptoms of facial neuralgia and one of the ordinary symptoms of disease in the petrosal; retropharyngeal abscess, general sinus thrombosis with slight impairment of cerebration. Death occurred after three months. There were present rigor and high temperature without apparent cause, and neuralgia of the right fifth nerve for ten days, and a septic condition resembling sinus thrombosis for six weeks. The abscess appeared suddenly in the right posterior pharynx. Six weeks later discharge from the right ear occurred together with

paralysis of the right leg and death. The necropsy showed antrum and general mastoid disease, sigmoid and general sinus thrombosis, which extended into the cortex of the left hemisphere. [T. L. C.]

2.—Morris Manges reports 6 cases of typhoid fever complicated by pharyngeal diphtheria. Five out of six cases finally recovered. As a rule the prognosis in this complication is gloomy, especially in children. The diphtheria antitoxin was well borne in all of the author's cases. [T. L. C.]

4.—Theodore Diller discusses the means of recognition of **tabes dorsalis**. The following leading symptoms he names in the order of their importance: (1) Failure of knee-jerks; (2) Romberg symptom; (3) Argyll Robertson pupil; (4) Lightning pains; (5) Loss of functions of the bladder or sexual organs. With the presence of any three of these symptoms the diagnosis may be made with certainty. And in the presence of any two with probability, when evidence pointing to multiple neuritis, parietic dementia or cerebrospinal syphilis is absent. Among the important secondary symptoms or signs are, (a) paresis, anesthesia or analgesia of the legs. (b) Locomotor ataxia. (c) Transient ocular palsies. (d) Paresthesia in the ulnar distribution, and (e) Optic atrophy. With the presence of two of the cardinal signs and one of the secondary signs, Diller believes the diagnosis may be made with certainty. With the presence of two of the secondary and only one of the primary, it may also be made, and even in the absence of all of the cardinal symptoms. [T. L. C.]

6.—John A. Hawkins, after discussing the various operations for the relief of **hemorrhoids**, describes a method and an instrument of his own which he has employed with great satisfaction. The instrument is a long, thin-bladed, tongue-and-grooved forceps. The hemorrhoid is grasped with this instrument and then cut off close to its blades. A suture of catgut is then started at the upper part of the base of the pile and carried as a whipstitch over the instrument until the lower portion of the pedicle is reached. The forceps is removed and the suture tightened. The author says that he has never had any hemorrhage or complication to follow this method of operation. [J. H. G.]

ANNALES DE GYNECOLOGIE ET D'OBSTETRIQUE.

January, 1901.

1. Omphalotripsy (umbilical infections). PORAK.
2. Cephalhematoma. QUEIREL.
3. Report on the Relationship between the Mental Development and the Functional Development in Young American Girls. Analysis of 12,000 Cases of First Menstruation. A Preliminary Study. G. J. ENGLEMAN.
4. Rachidian Anesthesia by Cocain applied to Labor. J. DUPAIGNE.
5. Blood-Infections in Nursing Infants. M. DELESTRE.

1.—Porak remarks that **umbilical infection** holds a much a much more considerable space in the pathology of the new-born than is usually accorded. Durante, who has made some researches on the subject, has concluded that umbilical infection is of frequent occurrence and considerable gravity. Rigorous antiseptics comprising dressings placed over the umbilical region require considerable time from the accouchur, while omphalotripsy, which is quicker, gives excellent results. Porak gives a comprehensive review of the anatomy of the umbilical region, and especially of the umbilical ring. He remarks that the skin terminates abruptly by a border sometimes parallel to the plane of the abdominal wall, but ordinarily obliquely. The umbilical ring is composed of the elements of the cord which are prolonged into it, namely, the mucous tissue of the cord, arteries and veins. The region is very rich in blood-vessels and in lymphatic vessels. The former are especially abundant in the skin level on the margin of which they form a plexus. Very frequently after ligation of the cord, owing to the slow separation that follows, septic changes will occur. Fungosities, omphalitis, and abnormal cicatrization constitute some very frequent complications arising during this process of separation. Porak claims that separation of the cord occurs much sooner after omphalotripsy than after ligation, and that this process will be influenced by the different forms of dressing. He gives tables showing the frequency of complications following

the two methods of treating the stump: by omphalotripsy and by ligation, and concludes that the former gives better results. [W. A. N. D.]

2.—Queirel gives an interesting article on **cephalohematoma**, which he mentions as one of the risks through which the child must pass during labor. Usually the tumor is single, but exceptionally it may be double, appearing at two symmetrical points on the parietal bones. It is difficult to give the precise proportion of frequency of this complication. The tumor consists of an infusion of blood between the periosteum and bone, forming either two projections over the parietal bosses, or more commonly a single projection upon one side. It is important to distinguish this condition from a sero-sanguinolent effusion which is much more common, and which is present at birth. This tumor is soft, but less fluctuating, and can be indented by the finger as in edema. It appears on the presenting portion of the fetus, therefore is formed before its expulsion and disappears shortly after birth—within one or two days. It never limits itself, as does the cephalohematoma, to the border of the bones. The characteristics of the cerosanguinolent tumors are exactly opposite to those of cephalohematoma. It is due to a circular compression at the base of the part which corresponds to the ring of the pelvis during engagement, and always appears before the presenting part. As to the prognosis of cephalohematoma, it is always favorable. The tumor usually disappears spontaneously from two to six months, or it may be a year after birth. At times its disappearance is much more abrupt, but as a rule the progress toward cure is slow, because the vitality of the part has been weakened and blood is not absorbed as quickly as a simple serous effusion. [W. A. N. D.]

3.—Engelmann has made an analysis of 12,000 cases of the **first menstruation** in young American girls covering a period of several years. He has given especial attention to the mental development of these girls, a factor which he claims has been largely neglected, and which he believes exercises a marked influence upon the functional development of the girls. The intimate relationship existing between the nervous system and the reproductive organs is one of the characteristics of the feminine organism and their reciprocal influence is profound. Of the 12,000 cases examined Engelmann has collected himself 6549. He has found that the mental development as a primitive factor determines precocity or retards the establishment of the menstruation. Race and heredity exercise but slight influence upon the function. He has also noted that in all its existence the development of puberty is a little, but very little, earlier in the country girl than in the working girl in town, no doubt because of the insufficient nourishment and the poor air which the laboring classes of large cities suffer from. Of all the influences, therefore, acting upon the development of puberty, the most important is the nervous: the mental state, the mental development, mental activity, and the nervous stimulus are especially active in influencing this function. [W. A. N. D.]

4.—Dupaigne practiced for a month in 1900 the application of **rachidian anesthesia by cocaine in labor**, acting under the suggestion of Tuffier. He claims that he has verified its possibility and innocuousness. Two conditions are indispensable for obtaining these results, namely, the independence of the uterine contraction and the extension of the anesthesia to the pains corresponding to this contraction. He claims that rachidian anesthesia, while altering in a certain proportion voluntary contraction of muscles, still more so affects the uterine contractions. The independence of the nervous ganglions renders this result possible. He also remarks that the anesthesia is complete for every form of labor pains, namely, the pains of uterine contraction and of dilatation of the neck, the lumbar radiations, pelvic and perineal compression, vulvular distension, tears, muscular cramps of the lower extremities, manual expression, touch, irrigations, sutures, when these are necessary, and that it even extends to all obstetrical operations. In a word, he claims that labor may be ideal for the woman. He also believes that the method is perfectly safe under all circumstances. [W. A. N. D.]

5.—During his service in Hutinal's wards in the Hospital for Children, Delestre has examined into the frequency of **blood infections in children** in general, particularly in those who are nursing, and principally in children born before term, to the latter of which he has especially devoted himself. His method of making examinations was as fol-

lows: When a child appeared sufficiently ill for it to seem that death would follow in a few days, or even a few hours, he drew from its veins 2 c.cm. of blood, which he submitted to examination. Special care was taken to disinfect the hands in doing this, and also the flap of the ear from which the blood was drawn. The parts were washed with alcohol and ether and a small incision made with an aseptic bistoury. This was repeated on successive days, and when the child died a certain quantity of blood was removed from the heart and cultures in gelatine and bouillon made. He does not believe that it is impossible to absolutely disinfect the skin, especially in these children, as has been claimed by some. The only precaution is to use an aseptic Brevaz syringe in withdrawing the blood. In 40 children of from a few days to 4 years of age believed to be infected, and from whom a bacteriological examination of the blood was made, 32 died and 8 recovered. Of the eight who recovered seven gave negative results; the other showed in three successive examinations the bacillus of Pfeiffer. Of the 32 children who died, ten gave negative results and 22 positive results. Of the latter there were five in whom the blood had been examined only during life, but upon whom no autopsy had been practiced; nine in whom the blood had not been examined during life and after death; and eight in whom the blood had been examined only immediately after death. The microorganisms discovered were in their order of frequency, the streptococcus eight times, the staphylococcus five times, the colon bacillus five times, the pneumococcus once, the bacillus of Pfeiffer once, the colon bacillus and Pfeiffer's bacillus once, and uncertain cocco-bacilli once. Of the 19 cases which died early 15 had microbes in the blood and four had none, which gives a percentage of 73.5-10%. Of the 15 cases the streptococcus was found six times and the collibacillus five times, staphylococcus once, pneumococcus once, Pfeiffer's bacillus once and the colon-bacillus and Pfeiffer's bacillus once. It would appear, therefore, that premature children are especially subject to the action of the streptococcus and of the bacterium coll., and less to the action of the staphylococcus, while the susceptibility to the latter microbe becomes greater in nursing babies of some months. [W. A. N. D.]

7. Recurrence of Ectopic Pregnancy. M. CHAPOT-REVOST.
8. Primary Tuberculosis of the Vagina and a Case Cured by Surgical Treatment. M. JORFIDA.

1.—Mauclaire remarks that several principal factors must be taken into consideration in order to explain uterine deviations. These are: (1) Ptosis generalized to all the abdominal viscera or localized to the ligaments and organs which maintain the fixity of the uterus. (2) Inflammatory lesions, congestive or infectious, of the uterine cavity, and very many deviations are without doubt the result of uterine infections; (3) Anatomic lesions of the deviated uteri, which are consecutive to ligamentous relaxation; to these may be added vasculo-nervous lesions which may be primary; and congenital deviations in a certain number of cases. Antelexions of the uterus are of several varieties. Thus, there is an antelexion of the body in which the axis of the neck is normal but the body is inclined anteriorly; antelexion of the neck in which the body is normal but the neck is carried anteriorly; and antelexion of the neck and of the body, the two segments of the uterus making a very acute opening anteriorly. The angle of flexion may, therefore, be made either opening by the body or by the neck or at the level of the isthmus, and this angle may be obtuse, right, or acute. The antelexion may be combined with

an anteversion, a retroversion, a latero-version, a latero-position or a latero-flexion. A number of operations have been suggested for the cure of anteversion. Some correct the cervical stenosis with or without a shortening of the neck. These are: crucial incision of the external orifice (Gaillard Thomas); bi-lateral dissection of the cervical canal (Simpson); antero-posterior dissection of the neck (Sims); conical excision of the posterior lip (Küster); commissural excision of the neck (Pozzi); and cervical amputation (Schröder). [W. A. N. D.]

2.—Fieux gives a scientific study of a ruptured tubal pregnancy at the second month in which an urgent laparotomy was performed. He has made a careful anatomical examination of the ruptured tube, which was on the right side. Examination showed to the right of the uterus a hard tumor adherent to the lateral cul-de-sac, which it had partly effaced, and extended thence to the anterior cul-de-sac. During the process of laparotomy peritoneal irrigation was maintained. He insists in such cases upon urgent intervention as soon after the diagnosis is made as is possible. His examination of the specimen was made both macroscopically and microscopically, and full notes are given. The specimen was found to be 77 days old. The rupture occurred on the posterior aspect of the ampullary region of the tube. [W. A. N. D.]

3.—Ségon reports a case of uterine pregnancy which was mistaken for an extrauterine pregnancy because of a fixation of the uterus in the position of left latero-version. The operation was performed, the true condition discovered, the uterus freed from its abnormal condition and replaced, and the patient entered a normal convalescence. The pregnancy continued without interruption but was ultimately discontinued by surgical interference, following an attempted abortion seven weeks after the operation. [W. A. N. D.]

4.—Varnier reports a case of pregnant uterus resting in the position of lateroflexion, which was mistaken for an ovarian cyst. Notwithstanding laparotomy the pregnancy continued to term and the patient was delivered of a living child weighing 3,500 grams. He remarks that lateroflexion of the pregnant uterus may be confounded with ectopic pregnancy, ovarian cyst, or salpingitis. He agrees with Mauriceau in the importance of making the diagnosis as early as possible in order that the displacement may be corrected. As to treatment the expectant plan may be adopted or, if the flexion is so strong and irreducible as to be incompatible with the normal evolution of the pregnancy, an exploratory incision should be performed and the uterus freed. [W. A. N. D.]

5.—Routier records a case of right-sided lateroflexion of the pregnant uterus which was mistaken for an extrauterine pregnancy. Laparotomy was performed, the uterus was replaced but abortion followed. The patient made an uninterrupted recovery otherwise. [W. A. N. D.]

6.—Coelho in 1896 presented to the Congress at Geneva the results of 15 vagino-fixations which he had made up to that time while performing 45 anterior colpotomies. Up to the present time he has performed 98 anterior colpotomies and 43 vagino-fixations with but a single fatal case. The simple vaginal fixations without treatment of other lesions have numbered 11. From 1895 he had attached the uterus to the vagina at 3 points, but since 1898 he has followed the method perfected by Dührssen. He makes now a single fixation, the thread passing through the uterine wall at the level of the insertion of the tubes and traversing the upper extremity of the vaginal incision and the peritoneal origin of the vesicouterine fold. By this arrangement he claims that difficulties during parturition are prevented and the cure of the retrodisplacement is accomplished without danger of reproduction following subsequent labor. He makes the vaginofixation immediately after opening the peritoneum or after treating the existing lesions, according as to whether the retrodeviation is simple or complicated. [W. A. N. D.]

7.—Chapet-Prévost records a case of recurrent extrauterine pregnancy in a woman, 30 years of age. The patient first menstruated at 18 years of age and always suffered with anti-dysmenorrhea. She was married when 28 years old and aborted a month and a half later without appreciable cause. Two months and a half later she had another abortion. Her menses returning 25 days after the second abortion she placed herself under the care of a specialist,

fearing a third pregnancy which might result as had the other two. The menstruation which usually lasted 7 or 8 days, did not return in July 1894. Another pregnancy soon followed and in October she experienced the first fetal movements, which continued until March 13, 1895. They then ceased and severe pains commenced, simulating labor pains. The physician who was called in 2 days after the first pains, declared there was no reason why he should continue his services. These pains continued at intervals for a month. Another physician was then called in and on examination discovered a mass which was diagnosed as a uterine fibroma. Chapot-Prévost saw her on the 12th of August, at which time the abdominal extension was about that of 7 months of pregnancy. However, the uterine sound measured scarcely $7\frac{1}{2}$ cm. He made the diagnosis of ectopic pregnancy and performed the operation on the 18th of August. After the primary incision in the median line of the abdominal wall a tumor was discovered which was inclined a little to the right. This contained a fetus which was extracted. The placenta was implanted upon a large part of the anterior face of the uterus, upon a portion of the bladder, and, extending to the left of these two organs, was attached to the posterior aspect of the abdominal wall. It was removed and the patient made a normal recovery. On October 9th, 1896, one year and one month after this operation, the patient returned, believing herself again pregnant. Examination showed under the abdominal wall a fetus corresponding to a pregnancy of five months, movements of which could be readily detected under the skin. In the seventh month of this pregnancy severe pains came on associated with uterine hemorrhage. Fetal movements stopped and one month later a second laparotomy was performed. A male fetus was removed from a cyst implanted upon the opposite side of the abdominal cavity and upon the aspect of the right ovary and tubal, the ileocecal appendix, upon a portion of the cecum and the large intestine and upon the posterior face of the anterior wall of the uterus. This was removed and the patient made a good recovery. [W. A. N. D.]

8.—Jorfida reports a case of primary tuberculosis of the vagina in a young married woman, 23 years of age, who apparently gave no hereditary history of tuberculosis. Beyond the ordinary exanthemata of childhood she had had no disease. Her menstruation had been regular in its appearance and duration. She had been married a year and a half and had given birth to one child at term, which had a weight a little above the average after a spontaneous labor. There had, however, been a tear in the posterior commissure. During the two months following labor she had not suffered from any inconvenience. After this, however, she commenced to notice a sensation of burning in the external genitalia which became more severe and even painful at the menstrual epochs. She also noticed a greenish discharge, slight at first but becoming more and more abundant. Notwithstanding this condition she did not at once apply for treatment. Twenty days before she presented herself she noticed evening elevations of temperature preceded by chills and at the same time she discovered a tumefaction in the left inguino-crural region, which suddenly increased in volume. Ten days after this appeared, a similar tumor formed in the right inguino-crural region. This was followed by an increase in size of the labia, particularly of the right labium major. Examination showed an edema of the parts which pitted on pressure and were covered with an abundant greenish secretion. Numerous ulcerations covered the vulva and the vagina, these being more marked and more extensive at the posterior commissure and in the anterior portion of the vagina. At the vulvar commissure there existed a solution of continuity the size of a two-centime piece elongated in its transverse diameter and with irregular and broken borders. The other ulcers were smaller and mainly on the posterior vaginal wall. The vaginal culs-de-sac were free from the ulcerated process, as was also the cervix uteri which was somewhat hypertrophied and reddened. Under appropriate treatment, consisting of free vaginal irrigations with a salicylated solution and bichlorid of mercury, no improvement was noted. The tumefactions were then extirpated and the crural hernia closed by Tricomi's method; with the exception of a fistulous tract in the left side, which persisted for more than a month, the parts rapidly healed. The vaginal ulcerations were cauterized with iodine and silver nitrate, and a tampon of iodoform gauze was introduced. The patient made a complete recovery. [W. A. N. D.]

MUENCHENER MEDICINISCHE WOCHENSCHRIFT.

March 30th, 1901.

1. The Etiology and Experimental Production of Cirrhosis of the Liver. MARCKWALD.
2. A case of Mixed Cirrhosis of the Liver With an Acute Course. ULLMAN.
3. Plasmon-Tropon. HESS.
4. The Influence of Coal Upon the Tubercle Bacillus. PAPASOTIRIU.
5. The Equilibrium and Hearing Organs of the Japanese Dancing Mouse. PANSE.
6. A Foreign Body in the Lung. SPIESS.
7. A Rare Case of Foreign Body in the Bronchial Tubes. DIEHL.
8. The Natural Immunization of Tuberculous Families. REIBMAYR.
9. Report of the Medical Polyclinic in Munich in the Year 1900. MORITZ.

1.—Marckwald has performed a number of experiments upon frogs in order to determine to what extent the degeneration of the parenchymatous cells of the liver tends to produce the cirrhotic condition. It was found that antipyrin injected hypodermatically into the animals produced a degeneration of the liver cells that was more or less rapid according to the dose and the size of the animal. If very small doses were employed the degeneration was exceedingly gradual. In the first series of frogs this degeneration took place without any increase in the connective tissue, a fact that the author explains by supposing that the poor condition of the frog's nutrition resulting from their refusal of all food in captivity, prevented the proliferation of the tissue. He therefore fed artificially a number of frogs and subjected them to the same treatment. He found that the connective tissue showed marked hyperplasia. He therefore regards the cirrhotic change as conservative and not destructive. [J. S.]

2.—Ullman reports a case of a man 53 years of age, who had taken from 1.5 to 2 liters of "Schnaps" daily for many years. He appeared to be perfectly healthy until he was suddenly attacked by a causeless vomiting and diarrhea, loss of appetite, and chilly sensations. There was then a moderate icterus, and the development of ascites and epistaxis, but throughout the case there was no fever. A puncture of the abdominal wall withdrew 2,500 ccm. of yellow fluid with a specific weight of 1.009. The patient died and at the autopsy, in addition to myocarditis, enlargement of the spleen, intense congestion of the kidneys, there was great enlargement of the liver, which was granular and hard. Microscopically it was found that the connective tissue was very irregularly hyperplastic, and that there was even some proliferation of the hepatic cells. The case is remarkable on account of its rapid course. The etiology is very obscure, that is to say, the alcohol probably acted largely as a predisposing factor. [J. S.]

3.—Hess has performed a number of experiments with plasmon and tropon in order to determine whether extirpation of the pancreas was more severe than simple transplantation. It was found that total extirpation caused a loss of 56.8% of the nutritional material, whereas in extirpation with transplantation, although under those circumstances the pancreas no longer connected with the intestines, the loss was only 53.3%. A few other experiments gave similar results. [J. S.]

4.—Papasotiriu has performed a number of experiments in order to determine whether charcoal has any inhibitory action upon the growth of the tubercle bacillus, or the pseudo-tubercle bacillus, the so-called mykobacterium lacticola. In the first experiments with the latter micro-organism it was found that a proportion of more than 10% of charcoal had a slight inhibitory action upon the growth of the germ. As, however, subsequent experiments showed that no inhibitory action occurred either toward this germ or toward the tubercle bacillus the author concludes that carbon is not an antiseptic. [J. S.]

5.—Panse has made a careful study of the hearing organ of the dancing mouse of Japan in order to determine whether it or the semi-circular canals exhibit any diversion from the usual type, that would serve to explain the absence of vertigo upon rotation. He found that there was absolutely no morphological peculiarity whatever. The hearing organ of this mouse resembles in all respects that of the ordinary house mouse. However, he did find

a small accumulation of calcium crystals in the membrane of the oval window, but as this also appeared in the ear of the mouse produced by crossing a common mouse with a dancing mouse, he concluded that, as this off-spring did not rotate, the crystals were not of any significance. [J. S.]

6.—Spiess reports the case of a boy 17 years of age who swallowed a bone button. Aside from a slight diminution of the respiratory sounds this produced no alteration for five years. Then the patient suffered from dyspnea, pain in the left side, and cough with expectoration. As it appeared that the foreign body, which still remained in the lung, had produced a severe inflammation, an effort was made to remove it through a tracheotomy wound. The position of the button was first determined by a Roentgen ray picture and then the bronchioscope employed. Through this it was possible to see a small opening in the main bronchus that was almost completely filled with a mucopurulent fluid that was not expelled by coughing. The sound in passing through this opening came in contact with a hard body. It being impossible to withdraw the body with forceps, other means were tried—passing a thread around it, or catching it upon a blunt hook. All these failed and the patient finally died of pulmonary tuberculosis 6½ years after inspiring the button. At the autopsy the button was found lying in a small cavity just inside the main bronchus, entirely non-adherent. No adhesions were found between the lung and the parietal pleura, and therefore an external operation would have been a failure. Spiess calls attention to the extreme ease with which the bronchioscope can be employed if a drop of a 10% solution of cocaine is allowed from time to time to trickle down the mucous membrane of the trachea. [J. S.]

7.—Diehl reports the case of a woman, who, as a result of an attempt at suicide, had so injured the trachea and larynx that it was necessary to employ a permanent tracheotomy tube. This was broken, and the patient was given another, which, however, was slightly too long, and therefore uncomfortable. Accordingly, when alone she reinserted the old tube, which slipped into the trachea and was pushed further down by the insertion of the new tube to relieve the dyspnea. It being impossible to remove the foreign body without operation, the patient was prepared for another tracheotomy, but fortunately she expelled the tube during a violent fit of coughing before this was performed. [J. S.]

8.—Reibmayr believes that the human race gradually acquires a greater or less degree of immunity against all infectious diseases, that consists in a certain constitutional alteration. He has endeavored for some years to discover what are the symptoms of this condition in the human race, and has finally reached the conclusion that a careful study of the genealogy in each individual leads to the most accurate results. In the treatment or prevention of tuberculosis the most important factor is the preservation of this immunity. [J. S.]

Obliteration of the Portal Vein.—Eugène Frélier. (*Gaz. Heb. de Med. et de Chir.*, April 7, 1901, 48^{me} Année, No. 28.) (Nancy Thesis, 1899-1900, No. 9). Frélier has studied 2 cases of obliteration of the portal vein. This condition may be produced by compression by tumors of all kinds and by thrombosis due to micro-organismal infection or to the extension of a carcinoma. It is favored by alcoholism, syphilis and all the diseases that may cause arteriosclerosis. As a consequence of this condition of the portal vein, anemia may be produced in the territory supplied by these veins in the liver, which may be followed by the disappearance of the liver cells and the production of periportal sclerosis. Congestions may also be produced in the tributaries of the portal vein with transudation and hypertrophy of the intestine or its walls, intestinal gangrene, ulcer of the stomach or duodenal ulcer. Obliteration of the portal vein is manifested by symptoms that are common to other affections, but which are characterized by the rapidity of their appearance, such as sharp pains, which usually appear about 3 weeks before death in the right hypochondriac or epigastric regions, voluminous ascites, increase in the size of the spleen, edema of the lower extremities, hematemeses, diarrhea, hemorrhoids, melena, decrease in the size of the liver and jaundice. Occurrence of hematemeses may be explained by venous stasis or by pneumogastric reflex. [J. M. S.]

WHAT I HAVE LEARNED FROM ONE HUNDRED AND SIXTY-ONE OPERATIONS FOR THE RELIEF OF SENILE HYPERTROPHY OF THE PROSTATE GLAND.*

By ORVILLE HORWITZ, B. S., M. D.,

of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College; Surgeon to the Philadelphia Hospital for Genito-Urinary Diseases, and to the Philadelphia Hospital for Skin and Syphilis.

If the student consults the standard text-books with a view to being enlightened as to the most satisfactory operation to be employed for the relief of senile hypertrophy of the prostate gland he will in most instances be doomed to disappointment. It is true, that many different operations designed for the relief of this condition will be found fully described, with a statement of the probable mortality attending each, but it is left to the option of the investigator to select the operation, which in his judgment will prove most efficacious. Not only do the books throw but little light on the subject, but the investigator finds himself in doubt as to the best method to be pursued under the many conditions that present themselves, he will also observe that the surgeons themselves differ widely as to the most suitable operation to be performed; each having its advocates as well as its detractors.

Although much has been written on the subject, giving rise to a vast amount of discussion regarding the merits of the various operative procedures suggested, it would appear that the truth is to be found in the fact that the writers themselves, as well as the profession at large, have been unable to arrive at any definite conclusion regarding the value of the various methods suggested. So far, there has been no attempt made to lay down any rule which will serve to guide the surgeon in his choice of operations, every individual seemingly relying upon his personal predilections.

An experience derived from the treatment of one hundred and sixty-one operations for the relief of prostatic hypertrophy has caused me to reach definite conclusions as to the relative value of the various methods suggested, and the difficulty that one may be expected to encounter, the mortality that attends each procedure, as well as the results that may be expected to be reached in each case.

The various operations performed are classified as follows:

	No. Operations.	No. Deaths.
Vasectomy,	28	—
Bilateral castration,	31	2
Supra-pubic cystotomy; bilateral castration two weeks later,	13	—
Supra-pubic cystotomy, permanent drainage,	33	—
Supra-pubic cystotomy with vasectomy,	5	—
Supra-pubic prostatectomy (prostate gland removed piece-meal),	2	—
Supra-pubic prostatectomy (Fuller's method),	3	1
Supra-pubic cystotomy combined with perineal section (Bellfield's method),	6	2

*Read before the American Association of Genitourinary Surgeons, at Old Point Comfort May 2, 1901.

Perineal prostatectomy (Alexander's method),	4	2
Perineal prostatectomy (Pyle's method),	1	1
Bottini's method,	1	—

By examining the foregoing classification it will be seen that of one hundred and sixty-one patients upon whom operations were performed eight died. In two, deaths ensued from bilateral castration, one died of uremia, and one from exhaustion; of the six remaining deaths, two followed suprapubic, and four followed perineal prostatectomy. Of the suprapubic operations one died from suppression of urine, and one from uremia. Of the deaths following perineal prostatectomy one died from sepsis, and one from uremia.

As a rule, the aged withstand operative procedure badly. The danger appears to be greatly increased if an extensive operation involving any portion of the genito-urinary apparatus becomes necessary. The dread of the operation frequently leads the patient to defer the ordeal until the symptoms indicate that further postponement is impracticable; unfortunately the delay is often due to the advice of the attending physician, who usually recommends that a course of palliative treatment be pursued as long as possible. Thus valuable time is lost, so that it is not unusual for the patient to be seen by the surgeon for the first time, when he is already debilitated and broken down, with poor digestion, diseased kidneys, chronically inflamed bladder, weak heart and suffering from pain and loss of sleep. Such an individual is hardly in a fit condition for even palliative treatment, still less for the radical operation, necessary for permanent relief.

Unfortunately it is just this class of cases that appeal most strongly to the surgeon for relief; feeble old men who have been suffering from the effects of prostatic obstruction complicated with chronic cystitis, secondary disease of the kidneys, from chronic urinary fever, or attacks of retention of urine, the passages of the catheter becoming difficult owing to the inflamed and congested condition of the prostatic gland. The physical condition of these persons is so wretched that any radical operation is not to be thought of.

The reason for allowing these unfortunate people to drift along, month after month, without attempting radical relief is possibly readily understood, when it is taken into consideration that vasectomy, or bilateral orchidectomy as a means of cure is repugnant to most men at the beginning of their prostatic trouble, and is consequently avoided. The other operations are either unsatisfactory or attended by high mortality, and are consequently postponed until surgical interference is an absolute necessity; this delay results in the condition of the individual being such as to render any operation dangerous.

I hope to be able to demonstrate that the Bottini galvano-caustic radical treatment of hypertrophy of the prostate gland proves in a large majority of cases to be entirely satisfactory. When this operation is performed a local anesthetic may be used; it is comparatively safe, especially if resorted to at the onset of the trouble; under favorable circumstances it confines the patient to his bed but for

a few days. When employed at the beginning of catheter life it may be regarded as a prophylactic measure, being followed in the majority of instances by absolute cure. From personal experience I am led to the conclusion that if cases of senile prostatic hypertrophy are operated on at the outset of the trouble, when the employment of the catheter is first indicated, the use of this instrument may in most cases be relinquished, and the evils attendant on the introduction of the tube averted, accompanied as it is by so much pain and discomfort; to say nothing of the chronic invalidism which is so frequently an attendant upon advanced prostatic obstruction.

As will be shown later on, the cases which were operated upon at an early period of the disease, resulted as favorably as could be desired; in every instance not only was the obstruction relieved, but the function of the bladder was restored to its healthy condition.

Bottini's method is likewise applicable to a large number of cases of advanced prostatic disease where want of vitality and poor health contraindicate the employment of more serious radical procedure; in these cases reliance is to be placed either on frequent catheterism or continuous drainage established by means of a suprapubic cystotomy. But in some cases of prostatic hypertrophy of long standing, even if the obstruction be entirely removed the function of the bladder will not be restored; this is especially the case where the folds of the mucosa become thickened, from inflammation, giving rise to the formation of ridges attended by hernial protrusions of the mucous membrane and a tendency to the formation of sacs or pouches. Reginald Harrison well describes this condition when he says: "Once these pouches are formed the muscular apparatus of the bladder is thrown out of gear, and no matter what is done the normal muscular contractility will never be restored. Nor will the muscular force be exerted in the right direction, consequently there will be always more or less residual urine." I have verified this statement in several prostatectomies, where the obstruction was entirely removed, and yet the individuals were quite unable to evacuate the contents of the bladder, and were compelled to rely upon the catheter for relief.

When this sacculated condition of the bladder exists a Bottini operation will remove the obstruction, whilst a double vasectomy will allow the catheter to be inserted without fear of giving rise to recurrent attacks of orchitis, a state so often attendant upon frequent catheterism.

The classification heretofore given will be followed when considering the results obtained in the number of operations recounted, together with the conclusion reached as to the relative value of the many methods employed, as well as the danger accruing from each.

Vasectomy.—Twenty-eight individuals were submitted to this operation, all of whom, with the exception of six, were over sixty-three years of age, and the sexual functions of all but six were in abeyance. Vasectomy was performed, whether the enlargement of the prostate was glandular or fibrous

in character. No deaths resulted from the operation. As a rule, the reported mortality from this operation is rather large, so that the result in each instance was watched with eagerness, and the fortunate termination was a gratifying surprise.

Of forty-nine reported operations, collected by Dr. A. C. Wood (White and Martin) there is a mortality of twelve per cent. Why the death rate from so simple an operation should be so great is incomprehensible, when it is remembered that in each case it was performed under the influence of local anesthesia, and that but a few minutes are needed to complete the whole process, which is attended by neither shock nor loss of blood.

Of six cases operated on under the age of sixty-three, the sexual power was preserved. At the time of the operation the individuals were at the entrance of "catheter life," about two and one-half ounces of urine remaining in each instance; the patients being compelled to arise more than once to discharge the contents of the bladder. In these cases vasectomy was selected as the least dangerous and simple method offering a chance of relief.

Sixteen cases were retained under observation: of this number four were greatly benefited; they were individuals between the ages of fifty-five and sixty-three, and were at the beginning of their prostatic troubles. The improvement in each was very gradual, and it was not until some five or six months had elapsed that any amelioration in the condition of the patient could be noted. Three of the cases still retain a slight quantity of residual urine, and employ a catheter once daily. One individual urinates six times during the day and once during the night; he has discontinued the use of the catheter. The patients in whom benefit has resulted from the operation were between the ages of fifty and sixty; they had suffered but for a short time from the symptoms of prostatic obstruction and their general physical condition was excellent. In three of the unsuccessful cases I have since performed the Bottini operation with most gratifying results. Three of the remaining cases have been operated upon by other surgeons; in two a prostatectomy was performed; one died and in one a permanent drainage was established by means of supra-pubic cystotomy, he is living and is comfortable. Four of the cases were not benefited and have to resort to the frequent use of the catheter for relief.

Prior to operation five of the patients suffered greatly from frequent attacks of relapsing orchitis; in each instance relief from this complication was obtained by the surgical procedures. In no instance was either atrophy of the testicle or any disturbance of the nervous system developed after division of the vasa deferentia. The operation was not followed by sexual weakness in any of those cases where the sexual powers had been retained. Thus out of the twenty-eight cases upon whom the operation was performed, but four were benefited, and these only after the lapse of a considerable period.

The results obtained lead me to the following conclusions:

1. As a curative measure vasectomy is of little value, and is not to be recommended.

2. The operation appears to be most effective when performed on patients between fifty and sixty years of age, in whom the prostatic enlargement is of the soft glandular variety. The genital organs of patients of this age are usually in a healthy condition, and the individuals usually object to any operation that is liable to interfere with their sexual functions.

3. The operation is serviceable in those cases where the physical condition of the individual renders him unfit to undergo surgical procedure, who will not submit to a more serious proceeding, who has to depend upon the frequent use of the catheter, or who suffers from periodical attacks of orchitis.

4. Sexual vigor is not diminished by the division of the vasa deferentia.

5. Atrophy of the testicle does not result from the operation.

Castration.—In forty-four cases bilateral orchidectomy was performed, irrespective of the character of the enlargement of the prostate gland. All the patients were men in advanced years, whose sexual powers had disappeared; in the majority, the heart was feeble, the arteries atheromatous, and they all suffered from general debility, the result of the wear and tear of prolonged misery. In a few, a far-advanced diseased condition of the bladder and kidney existed. Several had suffered from frequent attacks of retention of urine; catheterism was necessary in all; the insertion of the instrument was difficult and painful. In this class of patients prolonged anesthesia, with any serious operation in addition, would in all probability prove immediately fatal.

Experience has taught the profession that castration is not to be resorted to as a routine method of treatment. Its sphere of usefulness is unfortunately very much restricted. But in properly selected cases the relief afforded is often permanent and most gratifying. It is now generally conceded that it is only where the enlargement of the prostate is glandular in character, or where there is a chronic congestion of the organ, that relief is to be obtained by orchidectomy. Unfortunately, it is frequently impossible to distinguish the hypertrophy of a pure glandular type from that of the other varieties. When the enlarged prostate is hard and fibrous in character, due to hypertrophy of the stroma, atrophy does not follow castration, and no benefit is derived from the operation, under such circumstances some other method of giving relief must be employed. These views representing the judgment of the profession as to the value of the orchidectomy for the relief of prostatic hypertrophy are in accord with my own personal experience.

When an enlarged prostate, glandular in character, is engorged with blood, castration seems to give immediate relief. As a result the patient begins to void urine naturally and a catheter can be inserted with less difficulty and with less pain. On examination the prostate will seem to have perceptibly diminished in size, but it is questionable whether actual atrophy takes place until some months after the operation. If these cases are carefully watched it will be found that in most instances an ameliora-

tion of the urgent obstructive symptoms occurs immediately after the operation; then comes a period of abeyance when the condition remains quiescent for some time. The patient is enabled to evacuate a part of the urine contained in the bladder, but there is always a certain amount remaining in the viscus. Usually several months elapse before the residuum will be reduced to a minimum; then it will be found that the prostate gland is atrophied and shrunken. It is due to the subsidence of the congestion that immediate relief is given to the obstructive symptoms after operating upon suitable cases. The mortality from the operation where the general health is good has been proved to be about seven and one-half per cent. In old, feeble men, with general arterial sclerosis, who are suffering from pyelitis and chronic cystitis, the mortality reaches as high as eighteen per cent., being as great as that of prostatectomy under similar conditions. Castration, therefore, is an operation by no means free from danger. In none of the cases was there any disturbance of the nervous system following the operations. Quite a number of such annoying results, however, have been reported; hence the subsequent involvement of nervous complications is one of the dangers to be borne in mind when advising the operation. In two cases in which I considered the conditions were suitable for an orchidectomy other, more serious, operations were selected because the nervous temperaments of the individuals were so exalted and their dread of being castrated so great, that I feared that removal of the testicles might be followed by mental disturbances.

In five instances where patients were brought to the Jefferson Hospital suffering from retention of urine, due to prostatic obstruction, frequent unsuccessful efforts having been made to pass the catheter, on whom aspiration of the bladder had been performed several times, an immediate suprapubic cystotomy was performed and drainage established. In three the enlargement of the prostate was found to be glandular; the remaining two were fibrous. Two weeks later orchidectomy was performed on these cases with the result that in those instances where the prostate was of the soft variety perfect cure had resulted. In the two cases in which the growth was hard and fibrous no benefit resulted from castration, and suprapubic drainage had to be re-established.

The gratifying results sometimes obtained by castration in suitable cases of hypertrophy of the prostate is well illustrated by the brief account of a case seen in consultation with Dr. Edwin Graham in March, 1897. The patient was sixty-three years old. He stated that he had never had any venereal disease, but had suffered from a rapidly increasing irritability of the bladder for the past four years. Previous to my first visit he had been passing urine at intervals of about every two hours, day and night; which was sometimes attended with pain and spasm, at the neck of the bladder. The urine was thick and cloudy; sometimes a few drops of blood would follow the termination of the act. About thirty hours before I first saw him he had gotten his feet wet, which resulted in a desire to fre-

quently pass water. The insertion of the catheter was at first difficult, and finally impossible; retention of urine being complete. Every effort to pass different forms of catheter had been unsuccessful; aspiration had been performed twice. He was removed to the Jefferson Hospital. An examination revealed a large prostatic growth of the soft variety. As the introduction of an instrument into the bladder was impossible, recourse was had to an immediate suprapubic cystotomy. The prostate was found to be adenomatous in character, and to project into the bladder like a cork into the neck of a bottle. The bladder was the seat of chronic inflammation. Two weeks later castration was performed. When last seen, March, 1901, he was in robust health; had long ceased to use a catheter, passed urine about seven times daily and occasionally once at night. The urine was normal. The prostate was atrophied and there was about one drachm of residual urine in the bladder.

In four cases of glandular hypertrophy the obstruction was so great that a bicaude catheter (No. 9172) could be passed with difficulty; in these all symptoms of stone in the bladder were present; a double castration was performed. The obstructive symptoms were promptly relieved. Two weeks later a stone staff could easily be introduced and the stone detected. As the bladder in each case was in a state of advanced disease the calculi were removed by means of suprapubic cystotomy. These cases were reported in full in the *Therapeutic Gazette* for February 15, 1895.

In two other cases of glandular hypertrophy double castration was followed by the relief of all pathological symptoms. Of the 33 remaining cases two died, leaving 31 to be accounted for; 13 were lost sight of shortly after convalescing from the operation, but were unimproved when last heard from. In three of the remaining operations were performed by other surgeons. In one case I established a permanent suprapubic drainage, and in two others relief was procured by a Bottini operation. The 12 remaining cases are unimproved; the individuals refused to submit to any further operative interference, and so far as known at the present time they have still to resort to frequent catheterism for relief. So that out of forty-four castrations 9 who suffered from an adenoma of the prostate gland were practically cured. Five were operated on by others, unknown methods being employed. Three were reoperated on by myself. Ten still continue to rely on the use of the catheter. 13 were lost sight of, but were unimproved when last heard from, and two died. 33 cases were either unimproved, or so slightly benefited that other surgical procedure was resorted to. From the results obtained in the cases just detailed I think the following deductions are warrantable:

1. In selected cases, bilateral castration will always hold a place in genito-urinary surgery as a means of removing the obstruction caused by prostatic hypertrophy.

2. The operation is indicated in men of advanced years, whose sexual powers are lost, the overgrowth of the prostate being glandular in character, or who have reached that period of life where the passage

4. When the prostatic enlargement is fibrous in character no benefit is derived from the operation, and its employment under these circumstances is not to be recommended.

3. The primary effect of castration on the glandular prostatic hypertrophy is first to relieve congestion, and secondarily to cause atrophy.

4. When the prostatic enlargement is fibrous in character no benefit is derived from the operation, and its employment under these circumstances is not to be recommended.

5. Orchidectomy in very old subjects with extensive disease of the bladder and kidney is attended by a large mortality, and is a very serious operation.

Suprapubic Cystotomy.—Permanent drainage by means of suprapubic cystotomy was selected as a method of treatment in thirty-three cases. No deaths resulted. The operation was considered best suited to emergency cases where retention of urine existed; catheterism being impossible even after aspiration of the bladder had been performed in old men who were weak and debilitated, the passage of a catheter being difficult, and who were not in a suitable physical condition to withstand any severe radical measure for their relief. Twelve years have elapsed since the first case of this series was operated upon by me. Many of the individuals are still alive and comparatively comfortable. A specially designed metal suprapubic drainage tube was adjusted by means of which they were enabled to move about, their bladders being respectively capable of holding four ounces of urine without leakage. In two instances the prostate had reached such a size as to almost completely obliterate the bafond of the bladder, making it impossible to keep the drainage tube in situ. In these cases an apparatus was employed known as the Ransom urinal which has proved very satisfactory as a substitute for the metal drainage tube.

At best, this operation is merely a temporary expedient. In order that the drainage tube should be properly managed it is necessary that the individual should have a certain amount of intelligence which is wanting in many of the hospital patients.

Interruption of drainage.—Some of the subjects for suprapubic cystotomy. They are constantly worried and depressed by the presence of the tube and irritated and annoyed if the slightest amount of leakage takes place. In fact, the establishment of a permanent suprapubic fistula is a very unsatisfactory method of treatment and should be avoided if possible, although at the present time I have under my care several patients who are well satisfied with their condition, drainage having been established, and their general condition having been greatly improved.

In four cases upon whom suprapubic cystotomies had been performed, owing to the diseased condition of the bladder, daily insertion of catheters became necessary, in order to irrigate the viscus. These patients suffered from frequent attacks of orchitis for the relief of which recourse was had to a double vasectomy, which put an end to the disagreeable complication. In eleven cases stone in the bladder complicated the condition of prostatic hy-

protrusion; the foreign bodies were easily removed in each instance, without apparently adding to the danger of the condition. Four cases were in such a serious condition when they first came under my care, that suprapubic cystotomy became necessary; drainage was continued for four months, so as to justify operation for prostatectomy, which were successfully achieved. Cases of this description where a fistulous opening in the bladder is present are especial subjects for an Alexander operation. Suprapubic prostatectomy becomes a very difficult and even dangerous operation in those cases where a fistulous opening has been established temporarily to relieve the urgent symptoms. Particularly is this the case if the fistula has existed for a lengthened period. In attempting to reopen the bladder in order to reach the prostate gland it will be found that all the prevesical structures are so bound down by cicatricial tissue that it is well-nigh impossible to enlarge the opening sufficiently to reach the prostate gland without wounding the perineum. Conditions of this kind are most suitable for a perineal prostatectomy, or preferably a Bottini operation. When attempting to reach the bladder a transverse incision recommended by Trendelenberg should be made in conjunction with the one in the median line.

In three cases where retention of urine existed, strictures of small calibre complicated the prostatic obstruction. In two of the patients the contraction was located at the bulbo-membranous junction, the calibre being only sufficient to admit the passage of a small sized Gouley tunnel catheter, which could barely be inserted as far as the prostatic urethra. In these cases a perineal section was combined with the suprapubic cystotomy. In the third instance a stricture, the calibre of which was 12 M., was found to exist about the middle of the spongy portion of the urethra. After the bladder had been opened and drained, internal urethrotomy was performed. The patients made uninterrupted recoveries. Had the strictures in the membranous urethra proved impassable advantage would have been taken of the suprapubic opening to perform retrograde catheterism.

The mortality of the suprapubic cystotomy for drainage in chronic cystitis, malignant and tubercular disease of the bladder, prostate gland and removal of calculi varies between eleven and fourteen per cent. Why this high mortality should pertain in so simple and safe an operation it is difficult to determine. The operation can be performed in ten minutes; it is accompanied by little shock and scarcely any loss of blood and in urgent cases either spinal or local anesthesia can be employed. On three occasions I have opened the bladder, making use of a one per cent. solution of cocaine as a local anesthetic. I have performed suprapubic cystotomy for the purpose of exploring the bladder, establishing permanent drainage in conditions of cystitis, stone, tubercular, malignant disease and an obstructive prostatic hypertrophy one hundred and twenty-two times with one death, making a mortality of less than one per cent. The experience of my colleagues at the Jefferson Hospital has been similar to my own. Ansell, of Russia, published in the *Langenbeck's Archiv. für Klin. Chirurgie*, band 31, 1. und 2. heft., a report of one hundred

and two cases of suprapubic lithotomy, with but two deaths. I have come to regard the high operation for opening the bladder not only as one of the simplest, but one of the safest of surgical procedures. The high mortality sustained by some surgeons must be due to the fact that the patients were either not properly prepared for the operation; that the technique was faulty, or that a class of patients were selected whose physical condition was such that any surgical procedure would have been one of great danger. The indications for a suprapubic cystotomy in prostatic hypertrophy may be summarized as follows:

1. When retention exists and it is found impossible to evacuate the urine by the usual methods that are employed for that purpose.

2. As a temporary palliative means in those patients who have reached the "break-down period attending catheter life," whose resisting powers have disappeared and who suffer from secondary involvement of the bladder and kidneys; and whose condition is such to preclude the resorting to any more serious operation, but require immediate relief from the symptoms caused by the obstructing prostate gland.

3. In feeble old men, in whom the enlargement of the prostatic growth is fibrous in character, which renders the introduction of a catheter difficult, and the passage of the Bottini cautery knife impossible; in whom there is long standing chronic cystitis, with probably diseased kidneys, which preclude a prostatectomy, suprapubic cystotomy may be selected as the least dangerous and most satisfactory operation which can be employed.

(To be Continued.)

PROGRESS OF MEDICINE IN THE UNITED STATES DURING THE NINETEENTH CENTURY.

By CHARLES W. DULLES, M. D.,

of Philadelphia.

Lecturer on the History of Medicine, University of Pennsylvania.

A hundred years ago the United States was comprised of colonies scattered along the Atlantic coast, extending not very far from the seaboard, as we count distance now, with a total population of only about four million persons, with a few cities which, however important relatively, were absolutely small, the largest being Philadelphia with a population of about 65,000, among whom were reckoned 210 slaves. The customs and habits of the people were still those of the middle of the last century; and among medical men, the cloak, the queue and the cane still marked the dignity of the physician's office. The War of the Revolution, but recently ended, had left behind it a singular development of the art of surgery, and recent struggles with epidemics of the dreaded pestilence of yellow fever had served not only to cultivate the skill of physicians in this country, but also to bring into a bright light their courage and devotion to duty. It was a noble band of men who at that time represented the medical profession in America, in every way the peers of Washington and Franklin, and Hamilton

*An address delivered before the Contemporary Club of Philadelphia.

and Adams. Already, since the first colonists had landed, there had been a number of men who practised medicine in New England, and these were not unfrequently clergymen, who practised as well as they preached; while it is recorded of Governor Winthrop, of Massachusetts, that he was generous in distributing to his confiding fellow colonists what a writer of 1753 calls "his medicinal Van Helmont nostrums." Of medical men proper there had been in the colonies a number of considerable distinction, by far the greater part of whom were in Pennsylvania, where many things had combined to produce an exceptional state of culture and refinement. But this was the result of years of preparation. In the earlier history of the colonies medical science was at so low an ebb that Gabriel Thomas wrote from the colony of New Amstel, now New Castle, Delaware, about 1650: "Of Lawyers and Physicians I shall say nothing, because this country is very Peaceable and Healthy; long may it so continue, and never have occasion for the Tongue of the one nor the Pen of the other—both equally destructive to Men's Estates and Lives; besides, forsooth, they, Hangman-like, have a Licence to Murder and make Mischief." Nearly a hundred years later, as a contemporary writer asserts, in New York quacks abounded "like locusts in Egypt," and any man at his pleasure set up for physician, apothecary, or surgeon.

Philadelphia had the best of everything in those days, for William Penn brought over in the Welcome such physicians as Edward Jones, Griffith Owen and Thomas Wynne, and after them a number of other English physicians found Philadelphia a congenial place to come to; so it is no wonder that this part of the country soon passed far beyond those sections which had been settled long before it. One of the early physicians of Philadelphia was John Kearsley, of whose wealth and generosity a monument remains to us in Christ Church Hospital, to endow which he gave a large part of his fortune. Kearsley was a greater public benefactor from the training he gave to a number of young men who afterwards reached the highest distinction. These young men he not only drilled in the principles of physic, but also put to exercises of much plainer sort. His apprentices had no easy time, for, besides having to put up his pills and potions and carry them round to his patients, they had to clean his offices and do various menial services about his house. But he made men of them; and they were all heard from afterwards.

It is hard now to picture to oneself the conditions which existed in Philadelphia during the last century: the strip of houses along the Delaware shore, the smallness of those houses, the unlighted streets, the want of public conveyances, the watchmen stalking sleepily through the town at night, and greeting from time to time the doctor, wrapped in his cloak and supported by his cane, as he went on his errands of mercy. An old-fashioned representative of this day was Chovet, of romantic history and of sharp wit, which he often exercised in the coffee-houses at the expense of his townsmen—a Tory, and loving to trap and annoy even his friends who were devoted to the cause of Independence. Until old age carried him off, he went afoot: for he never rode or drove to his patients. Of him

they say, as Uncle Toby said of "our army in Flanders," that he swore terribly; and his habit furnished the ground for a story of a pointed repartee he once made to a member of the Society of Friends, who administered to him a mild reproof in regard to his profanity. It is said that, being caught in a rain storm at the house of a Quaker, Chovet desired of him the loan of a cloak. The Quaker, lending his cloak, took occasion to say: "Friend Chovet, I hope thee'll not swear in my cloak." The next day Chovet brought the cloak back; when, not satisfied to let well enough alone, the lender said: "Friend Chovet, I trust thee did not swear when thee had my cloak on." To which Chovet promptly answered: "No, I didn't swear; but I felt a damnable disposition to lie."

Then there was good old Thomas Cadwalader, to whom John Jones paid a high tribute in his preface to the first surgical tract published in this country, called: "Plain, Concise and Practical Remarks on the Treatment of Wounds and Fractures"—a little book put out in 1776 for the use of surgeons in the armies of the colonies. Cadwalader's principal literary essay was a monograph on the "Dry Gripes," but he will always be remembered as the first public instructor in anatomy in this country, preceding by a few years William Hunter, of Newport, who gave instruction on the same subject. After Cadwalader, William Shippen, Jr., lectured regularly on anatomy in Philadelphia, using in some of his lectures a magnificent set of drawings and models presented to the Pennsylvania Hospital by the famous Dr. Fothergill, of England. The following was the quaint announcement of these lectures: "Dr. Shippen's Anatomical Lectures will begin to-morrow evening, at six o'clock, at his father's house, in Fourth Street. Tickets for the course to be had of the Doctor, at five Pistoles each, and any gentlemen who incline to see the subject prepared for the lectures and learn the art of Dissecting, Injections, etc., are to pay five pistoles more." Dr. Shippen, being accused of robbing the churchyards in order to obtain bodies for his dissecting rooms, published in the *Pennsylvania Gazette*, October, 1765, a denial, in which he stated that "The bodies he dissected were of persons who had wilfully murdered themselves, or were publicly executed, except now and then one from the Potter's Field, whose death was owing to some particular disease, and that he never had one body from the church or any private burial place." About the same time Dr. Wright Post, who lectured on anatomy in New York, was assailed by what is known in history as the doctor's mob, which was excited by stories in regard to his robbing the graveyards to procure subjects for dissection.

By the beginning of the nineteenth century medical schools had been established: in Philadelphia in 1765, in New York in 1768, in Boston in 1782, in Dartmouth in 1798, and in Louisville, Ky., in 1800, while the Pennsylvania Hospital had been well started in its great work for humanity and medical science.

At that time Philadelphia was the undisputed centre of medical education in America, and Philadelphia physicians and surgeons excelled those of the rest of the country in number and attainments

and reputation. In this the medical profession in Philadelphia was only keeping step with the other departments of art, science, and industry. As Mr. Sidney Fisher says: "The first medical school, the first hospital, and the first dispensary ever known in North America were established in Philadelphia, which in colonial times and long afterwards was the centre of study for botany, astronomy, natural history and all the sciences that were pursued at that age." And, again: "The first fire-company was started there, the first circulating library, the first companies for insurance against fire, the first local periodical and the first bank." Philadelphia a hundred years ago furnished most of the material to form the American Philosophical Society, which for many years was to our country very much what the French Academy has been to France—the focus of learning of every sort. The University of Pennsylvania enjoyed the public recognition of Washington and his Cabinet, as it had enjoyed the recognition of the highest officials of the British Government before the War of the Revolution, and to its halls were gathered, from all parts of the country, and even from foreign lands, students who sat at the feet of men like Physick in surgery and Rush in internal medicine. It is to be feared that they bled and purged and sweated their patients with altogether too vigorous a hand. Some of the contemporaries of Rush did not hesitate to say that he killed more than he cured, and one of them, who took the pen-name of Peter Porcupine, assailed him with the coarsest venom, devoting successive numbers of a special periodical which he called the "Rush Light," and published in New York, to the abuse of this famous teacher. Physick had no enemies, and deserved the title of "Father of American Surgery," because of his fertility of resource, his skill in practice, and his wonderful kindness in dealing with his patients, though he showed his estimate of students of anatomy in those days by directing that his tomb should be carefully guarded against violation.

The great advance that has been made since the beginning of the nineteenth century in the department of internal medicine has been marked by contributions to our knowledge from all parts of the world. To this American physicians have contributed their full share. The greatest praise should be given to Dr. Joseph Parrish, of Philadelphia, who, in the typhus fever epidemic of 1812-13, boldly broke away from the practice of his predecessors and totally abandoned bleeding in his treatment, demonstrating by his success that this severe measure was unnecessary. Of other specific achievements of American medicine during this century should be mentioned the remarkable writings of Dr. Gerhard, of Philadelphia, in regard to diseases of the chest and the distinction between typhoid and ship, or typhus, fever, the achievements of Drs. Weyman and Bowditch, of Boston, in practising tapping of the chest for evacuating fluids produced in pleurisy, and the invention of the flexible stethoscope by Dr. Pennock, of Philadelphia; while no history of this period would be complete that did not include the names of such distinguished men as George B. Wood, one of the

most influential writers of the period and for many years Professor of Practice in the University of Pennsylvania, of René La Roche, whose study of yellow fever has never been excelled for accurate observation and keen judgment, of Alonzo Clark and Austin Flint, of New York, clinicians and teachers; of Isaac Ray, of Philadelphia, one of the most profound students of insanity that the world has ever produced, of the learned and polished Alfred Stillé, of that charming writer and able practitioner, J. M. Da Costa, and of that wonderful genius and public man, Dr. William Pepper, under whose guidance the University of Pennsylvania made such gigantic strides in material prosperity; while different American medical schools have been graced by the teachings of Draper and Dalton, Francis Gurney Smith and Austin Flint, Jr., in physiology, and of Oliver Wendell Holmes and S. Weir Mitchell, whose rank in literature has equalled that which they attained in teaching and practising medicine. In other branches of medical teaching Dewees and Hodge, both Professors in the University of Pennsylvania, published works which were long established text-books in this country and highly esteemed abroad.

The early period of the study of anatomy in America was marked by the industry, perseverance and talent of those who devoted themselves to this branch of work. Their worthy labors have been continued by worthy followers; so that the study of anatomy has been developed until it is conducted in this country as perfectly as anywhere in the world. The contrast between the last century and this may be seen by comparing the handful of students that gathered around Cadwalader and Shippen in their ill-lighted and narrow apartments, and the hundreds who in this city congregate in the spacious lecture halls of its medical schools, and have the opportunity of studying such beautiful specimens and preparations as are to be found in the Wistar Institute of Anatomy, a gift to the University of Pennsylvania, by General Isaac J. Wistar, in honor of his grand-uncle, Caspar Wistar, Jr., whose invaluable collection and that of Dr. William E. Horner formed the nucleus of what has now grown so great; while teachers of this fundamental branch of medical study in America can enjoy a justifiable pride when they recall that of their number was Joseph Pancoast and Joseph Leidy.

In this country chemistry has been studied faithfully from 1769, when Dr. Benjamin Rush became professor of this branch in the University of Pennsylvania, the first full recognition of the science in this country by any institution of learning. Chemists here feel a natural interest in the fact that Priestley, the discoverer of oxygen, who may be said to have released chemistry from the antiquated bonds of alchemy, when driven from England by religious persecution, came to America in 1794 and took up his abode in Northumberland, Pa., where he died in 1804, after having declined, on March 3, 1795, because he wished to live in the country, the Chair of Chemistry in the University of Pennsylvania, to which, on November 11, 1794, he had been elected. In 1802, Mr. (afterwards Dr.) Robert Hare, who in 1812 became Professor of Chemistry in the University of Pennsylvania, contributed to this

department of science the invention of the oxy-hydrogen blowpipe; while in 1808 Professors Silliman and Kingsley, of Yale College, published an account of the meteorite that fell at Weston, Conn., the year before—a paper which attracted widespread attention, and drew from Thomas Jefferson the oft-quoted remark that it was “easier to believe that two Yankee professors could lie, than to admit that stones fall from Heaven.” Among chemists that ought to be remembered is James Smithson, of England, who, in 1829, bequeathed his property to the United States to found an institution for the increase and diffusion of knowledge among men—the now famous Smithsonian Institution, at Washington.

The most shining achievements of the medical art in America during the nineteenth century were those in the line of surgery. At the very beginning of the century, we find that Physick, with his extraordinary genius, had adopted the use of what has since been universally employed under the term of animal ligatures. In his day, and unfortunately for long years after, the usual treatment of wounded blood-vessels was to tie them with silk or linen cords, and to leave one end of the ligature hanging out from the wound, so that it might be withdrawn after it had been separated from the blood-vessel by a process of ulceration. Only those who have seen this method employed can appreciate its disadvantages and dangers. Physick conceived the idea that he could introduce ligatures made of animal substance, which would be dissolved and come away, or could be withdrawn without the risks run when the customary material was used. Unfortunately, this idea was never fully developed in his day, and decades passed before the practice of surgery was revolutionized by the introduction of the catgut ligature.

There were many other surgeons in America who contributed to place the practice of surgery in this country in every respect on a level with, and in some respects above, that of any part of the world. As three hundred years ago the patriots of Holland adopted, and flaunted in the face of their enemies, the title of “Beggars,” which had been scornfully applied to them, so in this country it has long been possible to refer with pride to the taunt attributed to Sidney Smith, uttered in the early part of this century: “In the four quarters of the globe, who reads an American book? or goes to an American play? or looks upon an American picture or statue? What does the world yet owe to American physicians or surgeons?” Though this fling may be accounted for partly by the inexcusable ignorance of Sidney Smith in regard to the achievements that had then already been made by American physicians and surgeons, we have lived to see so different a situation, that we can now ask: In what part of the four quarters of the globe are not these tributes paid to American skill and genius? The Walhalla of the healing art would sadly miss the figures of Warren, Mott, Post, Dorsey, Gibson, McDowell, Horner, McClellan, Atlee, Pancoast, Gross and Agnew. There is not an operation in surgery in connection with which some one of these names is not crowned with an imperishable glory. There is no operation so delicate, none so dif-

ficult, that it has not been thoroughly mastered by American surgeons, while American surgeons have originated certain operations requiring the most astonishing combination of judgment, courage and conscience. It was Ephraim McDowell, of Kentucky, who, in 1809, first of all the world, did a deliberately planned ovariectomy, and in three successive and successful cases, proved the practicability of this operation which has saved countless lives. Since then it was the two Atlees, of Pennsylvania—Washington and John L.—who, by their indomitable courage, in the face of bitter opposition and violent abuse, placed this operation on a firm basis and completed the work which McDowell, to the great gain of mankind and the great glory of American surgery, had begun.

Of other special advances in the art of surgery might be named the improvements made in this country in the treatment of wounds and diseases of the contents of the abdomen. Nowhere in the world have more brilliant results been achieved than here in the management of those formerly almost invariably fatal conditions; while it is hard to estimate how much women owe to the skill and ingenuity of Marion Sims, who, coming from South Carolina to New York not only became a most conspicuous and successful operator, but also founded the first Women's Hospital in the world; while the invention of intubation of the larynx will forever preserve from oblivion the name of O'Dwyer, of New York.

The nineteenth century has seen remarkable advances in the science and art of medicine as shown in the establishment of medical societies, in the inauguration of instruction in veterinary medicine, and in the universally admitted first place America holds in the teaching and practising of dentistry. The greatest perfection has been attained in the construction and administration of hospitals, of museums, of libraries, and of laboratories, and a remarkably advanced position has taken in the training of women for the practice of medicine. Philadelphia has the first medical college ever established exclusively for women, whence has gone out a large number of women to carry the skill of the physician to their sisters sorely needing their help in foreign lands.

Probably the greatest single achievement of the nineteenth century was the application to surgery of what are called general anesthetics. Though for centuries surgeons had endeavored to lessen the pain of operations by the use of various drugs, some of which, we are told, were supposed to act by means of their odor, it was not until 1846 that what is now known as general anesthesia was properly practised. In 1799 Sir Humphry Davy inhaled nitrous oxide to quiet the pain of cutting a wisdom tooth; but it remained for an American dentist, Horace Wells, in 1844, to use this gas systematically; while in 1846 William Morton—who had learned the use of nitrous oxide gas from Wells—at the suggestion of Dr. Charles T. Jackson, first used ether for tooth-extraction and soon after succeeded in establishing its claims as a general anesthetic. Four years earlier—that is in 1842—an unpretending country practitioner, Dr. Crawford Long, of Athens, Georgia, who had observed the effect of

an accidental total anesthesia, produced by giving what was considered an overdose of ether by inhalation to a negro, employed this agent in the removal of a tumor, and afterwards several times, with entire success. But as he did not publish his operations at the time, it was not known that he had done them until the success of ether led to discussions as to priority in its use. It is clear that, whatever part others may have had in the development of this idea, it was William Morton to whom more than to any one else the world is indebted for it. He had the courage to propose to test the method in public; and on October 16, 1846, the first public operation under ether was done in the operating room of the Massachusetts General Hospital by Dr. John Collins Warren. The scene on this occasion was a most interesting one. The patient, surrounded by some of the most distinguished surgeons of Boston and New York, was instructed by Morton to breathe deep and long and to have confidence in him. He soon became completely unconscious, and Morton, turning to Dr. Warren, said: "Your patient is ready." At the first incision there was no sign of pain; a pin could have been heard to fall, so intense was the silence. Dr. Warren quickly completed the operation, removing the tumor and placing the stitches. Still there was no sign of pain, the patient slumbering as peacefully as a child. Dr. Warren turned slowly from the recumbent figure, and scanning the eager faces about him said: "Gentlemen, *this* is no humbug." Thus was successfully inaugurated a practice which revolutionized surgery and has saved immeasurable suffering and countless lives. This glorious achievement belongs entirely to America and to the nineteenth century. Its description may fitly serve as a conclusion to this brief summary of what was then accomplished in the noble work of those devoted to the art of healing, of whom Whittier says:

"So stood of old the holy Christ
Amidst the suffering throng;
With whom his lightest touch sufficed
To make the weakest strong.

That healing gift he lends to them
Who use it in his name;
The power that filled his garment's hem
Is evermore the same.

The New Gynecological Pavilions of the Broca Hospital.

—Dr. Pozzi, the first Professor of Gynecology in the Paris Faculty of Medicine, is the chief surgeon of the new gynecological pavilions of the Broca Hospital, which have been recently opened. The new buildings are in three divisions, the dispensary, the wards, and the operating rooms. The dispensary is open daily, and is modern in appointment and detail. In the four wards there are 44 beds, and there exist 18 more, 6 alone, the rest two or three in a room. All the furnishings are easily sterilized. There are separate rooms for changing the dressings, adjoining the wards. The baths and water-closets are of the latest pattern; and there are running water and electric light. The amphitheatre is up-to-date in its equipment, in all particulars superior to any in France. Sterilizing and anesthetizing rooms, rooms for instruments and for aseptic operations adjoin it. It can be easily flooded from above. Beside the seats for the students, there is a special balcony for visitors. (*Gazette Medicale de Paris*, 1901, Nos. 16 and 17). [M. O.]

A NEW CLINOMETER FOR MEASURING TORSIONAL DEVIATIONS OF THE EYE, DELIMITING PARACENTRAL SCOTOMATA AND METAMORPHOPSIA AND DETECTING SIMULATION OF BLINDNESS.*

By ALEXANDER DUANE, M. D.,

OF NEW YORK.

Although the usefulness of the Maddox rod as a means of estimating torsion of the eyes has been signalized by Maddox himself,** and although some have employed the test for this purpose clinically,** I do not believe the advantages that it offers have been fully appreciated by the profession at large. The utility of being able to determine the degree of torsion in paralysis of one of the vertical muscles is obvious, and the Maddox rod is admirably adapted for accomplishing this in a simple and efficient manner. It would be equally applicable for the determination of a cyclophoria. But, apart from cases of paralysis, which are comparatively few, and apart from cases of cyclophoria, which in the present state of our knowledge must be characterized as supposititious, the test seems to have a much wider range of application. For it can serve to determine in any given case the ability of the eye to judge whether lines are truly vertical and horizontal or not, and whether two given intersecting lines really form a right angle or not. Having thus determined by actual measurement how near the truth the patient's estimates of these things are, we can then proceed to ascertain how far these estimates are affected by the addition of glasses. If his notions in this regard—i. e., of the directions and relations of horizontal and vertical lines—are much altered by the glasses, we may consider it as at least quite likely that such glasses, even if they seem otherwise correct, will produce distortion when worn. That such distortion not infrequently results from the use of cylindrical glasses, we all know. It causes the patient much annoyance. He is apt to complain of it a good deal, even when the glasses are in other respects acceptable. Hence it would be a very desirable thing if we had some means of predicting whether or not in any given case a distortion of this sort was likely to ensue with a correcting glass such as we wish to prescribe.

Description of the Clinometer.

To apply the Maddox rod to the determination of these problems, I have had constructed for me by Messrs. Gall and Lembke the following instrument, which, in accordance with the appropriate nomenclature of Dr. Stevens, I have denominated a *clinometer*.

It consists of two Maddox rods (the multiple pattern), each mounted so as to revolve freely in a frame composed of a square metal plate. Each plate has a spring catch *c*, enabling it to slide freely along

*Read before the Pan-American Congress in Havana, February, 1901.

**Maddox. "Tests and Studies of the Ocular Muscles," Chap. xiii.

***Dr. Weeks informs me that he has so used it.

A.

B.

the horizontal bar of a Stevens phorometer. One plate (A) is designed for the patient's right eye, the other (B) distinguished by being made of ruby glass, for the left. By this arrangement a Maddox rod may be placed before the right eye alone, the left alone, or before each simultaneously.

That side of the plate which is turned away from the patient bears a graduated arc, and the revolving piece containing the Maddox rod has two indexes, so disposed that when the index marked V is at zero and the phorometer bar is levelled, the line of light formed by the Maddox rod is strictly vertical, and when the index H is at zero, the line of light is horizontal. The Maddox rods are revolved by means of the handles, *b. b.*

Method of Using the Clinometer.

The way of using the instrument is as follows:

The patient is seated so as to face a small brilliant point of light on the other side of the room, and the room itself is darkened so as to prevent confusion with other sources of light. The patient is directed to look with his right eye through the right Maddox rod, which is then rotated until he says that the line of light formed by it appears vertical. (In making the test in this way, I generally screen the other eye, so as to eliminate the confusing effect of other vertical and horizontal lines in the room.) If, when the patient alleges the line of light to be vertical, the index V stands at zero or very close to it, we know that his vertical meridian is truly vertical. If, on the contrary, it should point to 8° on that portion of the arc above the zero mark (the portion marked on the instrument with the letter L), we would know that his vertical meridian was rotated by that amount to the *left*. Similarly, if the index pointed to 5° below the zero mark (toward the letter R upon the instrument), we would know that the vertical meridian was rotated 5° to the *right*.

The test is then repeated with the left eye alone (the right being covered), and afterward with both

eyes simultaneously. In the latter case, the two rods, one before the right eye, the other before the left, are turned until the two lines of light, one white, the other red, both appear vertical and either coincident or at least parallel.

The behavior of the eyes as regards vertical lines being thus determined, the same series of tests is then made for *horizontal lines*, the Maddox rods being turned until the patient says that the line of light is horizontal, and the amount of deviation from true horizontality being ascertained from the reading of the index H.

To determine the accuracy with which the patient estimates right angles, we place the Maddox rods before both eyes and turn the rods until the right (or white) line appears vertical and the left (or red) line appears horizontal. The reading of the index V on the right plate and of the index H on the left plate should be the same, or, at all events, not notably different. If there is a discrepancy of 5° or more between the readings, the indication is that the patient's estimate of perpendiculars is at fault, and that a true right angle would appear to him oblique, i. e., appreciably distorted.

To confirm this suspicion, we would set the right V index and the left H index at zero, and ask the patient if the lines now appeared truly perpendicular or not, and if not how we should change them.

Lastly, we may repeat the experiment by making the left (or red) line the vertical, and the right (white) line the horizontal one.

It is obvious that the apparatus may also be used for making the *ordinary Maddox rod test for heterophoria*. In this case one eye is kept uncovered, and either one of the sliding plates with its Maddox rod is brought before the other eye. The indexes H and V being successively set at zero, so that the line of light produced by the rod appears successively horizontal and vertical, we determine the degree of vertical and lateral deviation in the usual manner.

Precautions to be Observed.

Some experimentation with this apparatus has taught me the following facts with regard to its use:

While we naturally aim to have the patient with his eyes *in the primary position* when we are making the test, no essential error is caused if he tilts his head moderately to one side or rotates it moderately to the right or left. In my own case, neither inclining the head toward one shoulder nor rotating it laterally causes any appreciable tipping of the vertical line produced by the Maddox rod. When, however, I turn my head obliquely so as to look up and to the right or up and to the left, I get in extreme positions a torsion corresponding to Donders' law. But even then the torsion amounts to not more than 4° at the most. In the oblique positions in the lower field, the torsion seems to be not so marked.

These findings are quite in accordance with what we know of the torsion movements of the normal eye. With abnormal eyes, however, a greater variation in the torsion may be caused by variations in the position of the head, and hence it is well to start the examination with the eyes as nearly as may be in the primary position. Then if we find torsion of some considerable amount, we can by shifting the position of the head determine *whether the torsion varies decidedly in different directions of the gaze* and from this perhaps draw important conclusions as to the cause underlying the torsion.

Ametropia of high degree, unless corrected, vitiates to a certain degree the precision of the test, because in this case the line of light is converted into a broad, uneven band or into a series of separate beads, the situation and direction of which are not so easy to appreciate. This difficulty may be partially obviated by using for the source of light a very small luminous point instead of a broad flame.

As might be expected, I find that the judgments of verticalness and horizontality are *more accurate when the apparatus is used with both eyes*, so that two parallel lines are seen, than when it is used with one eye alone, the other being closed.

Experiments further show that, on the whole, judgments are about as *accurate for horizontal as they are for vertical lines*. Thus, out of 33 cases there were 16 that designated vertical and horizontal lines with equal precision; 9 designated vertical lines more accurately than horizontal; and 8 designated the horizontal lines more accurately.

As far as can be judged from the limited number of cases examined, the ability to distinguish the direction of lines with precision is *not more pronounced in one eye than in the other*. Sometimes the right eye was more accurate in its discriminations, sometimes the left; while in other cases still, both eyes showed equal ability.

Results of its Use in Normal Cases.

I have so far had occasion to apply the test in only 46 cases. Of these 34* may be characterized as perfectly normal. That is, in no case were the variations from the truth in the estimate of horizontality or verticalness ever greater than 3° for either eye tested separately, nor greater than 2° when both

eyes were used simultaneously; and the variation from parallelism when both eyes were used simultaneously was never greater than 2° . These were the maximum variations, and in many instances the patient's estimate was not more than 1° out of the way or was absolutely accurate. It seems likely, indeed, that when the test is carefully performed, the limit of observational error should not exceed 2° , and that any amount of torsion in excess of this, especially if constantly present, indicates a real tilting of the vertical meridian, i. e., a condition actually pathological.

I may say that the 34 patients in this series were of all ages, from six to sixty, and were taken as they came without regard to their intelligence or to any special aptitude that they showed for undergoing tests of this sort. As a matter of fact, some of the most accurate answers were given by those who had the least intelligence and training. All conditions of refraction were represented. Several of the patients had muscular anomalies (principally a convergence-insufficiency), but none had any pronounced vertical deviation, except a single case** which had a high degree of hyperphoria with deviation of both eyes up behind the screen.

Of the remaining cases, one (Case 35) showed at one time a torsion for horizontal lines of 4° or 5° in each eye. But, as even on this occasion, the vertical meridians of the two eyes remained parallel, and as subsequent examinations failed to reveal torsion of any amount in either eye, it is probable that this case was also normal, and that the single observation indicating an anomalous torsion was erroneous.

The same explanation may possibly apply to the following, although two examinations (one without and the other with the correcting glass) showed a somewhat marked torsion:

CASE 36.—Mrs. J. G. Torsion without her correcting glass was

For horizontal lines, R. eye— 2° ; L. eye 0° .*

For vertical lines, R. eye— 3.5° ; L. eye— 2° .

With her glass (R.— $0.75+1.75$ cyl. 90° ; L.— $+0.75$ cyl. 90° , it was

For horizontal lines R. eye— 1° ; L. eye— 1° .

For vertical lines R. eye— 3.5° ; L. eye,— 2° .

In the following cases, the moderate degree of torsion indicated may also have been simply an apparent, or, at most, a transient condition, although the consistency of the findings in both cases and the fact noted by the second patient that he could not draw perpendiculars accurately, are evidence in some degree that the relations of the vertical meridians were not altogether normal:

CASE 37.—Ernest S. T., age 40. Wearing for nearly four years R.— $0.50+1.75$ cyl. 90° , L.— $0.75+2.25$ cyl. 90° . With these has V of 15/15 in right eye, 15/20 in left. Marked convergence-excess with moderate divergence-insufficiency (representing the remains of a left strabismus convergens which existed in childhood). Binocular single vision with, however, a tendency, especially without his glasses, to troublesome homonymous diplopia. Both the tendency to diplopia and the convergence-excess have diminished in the four years during which he has been under observation.

Torsion for horizontal lines, Right eye— 2° , Left eye— 2° .

Torsion for vertical lines, Right eye— 2.5° , Left eye— 3° .

In estimating perpendiculars, says that the intersecting lines formed by the two Maddox rods are truly perpendicu-

*And another, examined since, with a paresis of the inferior rectus.

Throughout this paper the terms "right" and "left" are used in Helmholtz's sense to denote respectively right and left rotations of the vertical meridian.

*To these must be added 7 cases examined since.

lar and are respectively horizontal and vertical when the right H index is at -2° , and the left V index is at -4° . I. e., under all conditions there is a moderate *lævotorsion* of both eyes.

CASE 38.—Henry P., age, 47. Myopia of 5.5 and 6 D with slight astigmatism against the rule. Muscles practically normal.

Torsion for horizontal lines. Right eye— 2.5° ; Left eye— 2.5° .

Torsion for vertical lines. Right eye— 1° ; Left eye— 3° .

In estimating perpendiculars, calls the intersecting lines respectively horizontal and vertical when the right H index is at -1° and the left V index is at -3° .

Says that when he tries to draw lines with a ruler he makes the vertical lines slope too much to the left.

Effects of Uncorrected Ametropia.

In the next cases there was considerable uncorrected ametropia, which probably accounted for the indecisiveness of the tests.

CASE 39.—Annie G. Age 19. V.: R. 15/100; L. 15/50. Under homatropine shows R. $-0.75 + 4.00$ cyl. 110° ; L. $-0.75 + 4.00$ cyl. 70° .

Without glasses shows torsion:

For horizontal lines, R. eye 0° ; L. eye -2° .

For vertical lines, R. eye 0° to -5° ; L. eye 0° .

CASE 40.—Tinie Y. Age 18. Hyperopia and oblique astigmatism (R. $+1.75 + 1.50$ cyl. axis. 30° ; L. $+1.50 + 3.00$ cyl. axis 140°). On two different occasions shows without her correcting glasses a *lævotorsion* of 2° to 6° in the right eye and of 2° to 4° in the left eye, when examined with vertical lines, and a dextrotorsion of 2° to 3° in the R. eye and 0° to 1° in the left eye when examined with horizontal lines. Vertical meridians practically parallel. V.: R. 15/40; L. 15/70.

Torsion Produced by Ill-fitting Glasses.

In the following cases the torsion was probably attributable to ill-fitting glasses:

CASE 41.—Mrs. S. D. Myopia of 8 D, with some astigmatism against the rule. First test, September 21, 1900, showed torsion.

For horizontal lines, R. eye -1° to -4° ; L. eye -1.5° to -2.5° .

For vertical lines, R. eye 0° ; L. eye 0° .

Maximum variation from parallelism for horizontal lines 1.5° .

Maximum variation from parallelism for vertical lines 0° .

Second test, November 27, 1900, after using ill-fitting spherical glasses (-8 D), showed torsion and variation from parallelism as follows:

Without Correcting Glass.

For horizontal lines, R. eye -1° ; L. eye -3° .

For vertical lines, R. eye 0° to -4° ; L. eye -3° to -6° .

Variation from parallelism for horizontal lines, 2° .

Variation from parallelism for vertical lines, 3° .

With Her Own Glasses.

For horizontal lines R. eye -2° to -3° ; L. eye 0° .

For vertical lines R. eye -3° ; L. eye -4° .

Variation from parallelism for horizontal lines 2° .

Variation from parallelism for vertical lines 1° .

With -8 D Set in Trial Frame and Carefully Centered.

For horizontal lines R. eye 0° ; L. eye -4° .

For vertical lines R. eye -1° ; L. eye -4° .

Variations from parallelism for horizontal lines 3° .

Variations from parallelism for vertical lines 4° .

CASE 42.—M. R. Age 14. Using for several years R. $+4.50$ cyl. axis 90° ; L. $+5.50$ cyl. axis 90° . Right glass now bent, so that axis of cylinder is tilted inward. Left eye, whether with or without glass, shows no torsion of any amount; right eye shows without glasses torsion varying from 0° to $+8^{\circ}$, and with glasses torsion of 0° to $+5^{\circ}$. When the right glass is properly adjusted, torsion in right eye is found to vary from -2° to $+3^{\circ}$.

CASE 43.—Dr. E. S. Wearing R. $-0.75 - 5.00$ cyl. axis 35° ; L. $-1.75 - 4.25$ cyl. axis 165° . Astigmatism under-corrected in right eye, overcorrected in left (0.75 D). V: R 20/20; L 20/30. Right eye, with glasses and without, shows no special torsion, while left eye shows an extorsion of 2° to 5° . In binocular vision he showed little or no divergence of the vertical meridians when examined with horizontal lines, but a divergence of 4° of 5° (distorsion)

when examined with vertical lines. On re-examination, two months later, the relations were much more nearly normal, although there was still a decided tendency to *lævotorsion* in the left eye.

To be grouped in this same category are two of the cases classed as normal. In these two, the relations were, indeed, normal as long as no glasses were used, but seemed to become slightly abnormal when glasses were put on for the first time.

One was a myope of 1.75 D, who with the glass showed a slight *lævotorsion* (torsion of -2° or -3°) of both eyes, the vertical meridians remaining parallel; in the other, the correction of a moderate degree of oblique astigmatism (0.75 and 1.25 D) seemed to cause the vertical meridians to diverge about 3° .

True Torsion in Non-Paralytic Cases.

In the following case there seemed to be a true torsion, which was not dependent upon paresis of any of the ocular muscles:

CASE 44.—Dr. J. C. C. Very slight myopic astigmatism (not over 0.25 D). Esophoria moderate for distance and near (slight convergence—excess). No limitation of the ocular movements, and no diplopia anywhere in the field of fixation (true binocular single vision everywhere).

Declination for vertical lines, Right eye— 1° ; Left eye— 5° .

Declination for vertical lines, Right eye— 1° ; Left eye— 5° .

When tested for perpendiculars, he declares the intersecting lines formed by the two Maddox rods to be truly perpendicular and respectively horizontal and vertical, when the right H index is at $+1^{\circ}$ and the left V index is at -4.5° . I. e., he still shows marked *lævotorsion* of the left eye, and his estimate of perpendiculars is 5.5° in error.

The deflection in this case was apparently constant, and was too great to be attributed to observational error.

Application of the Clinometer in Cases of Paralysis.

The following cases show the application of the instrument in measuring the obliquity of the images due to paralysis or spasm of the ocular muscles:

CASE 45.—Mrs. J. D. Postoperative insufficiency of right superior recti (old) and of left superior and inferior recti (recent). Compensatory spasm of obliques, especially of right inferior oblique, producing varying and temporary, but very annoying obliquity of objects, particularly those seen with the right eye. In August, 1900, showed for both vertical and horizontal lines a torsion of $+8^{\circ}$ in the right eye and of -3° in the left, giving a divergence of the vertical meridians (distorsion) of 11° . In the latter part of August the distorsion had diminished to 3° . In October, when she again noticed a slant in the images, especially those seen with the right eye, the clinometer showed that the torsion for this eye was 0° for horizontal lines and only from $+1^{\circ}$ to $+3^{\circ}$ for vertical lines, while in the left eye it was -5° for horizontal lines and -1° to -2° for vertical lines (the distorsion being thus from 3° to 5°).

CASE 46.—Frank R. Age 20. Traumatic paralysis of left superior rectus (completed with traumatic enophthalmus). Gets characteristic diplopia with characteristic tilting of the double images, but always declares that it is the image of the right eye that is tilted, while that of the left is straight. When tested with the clinometer, torsion for horizontal lines is 0° in the right eye, about -10° in the left (2 tests).

These cases are good illustrations of the fact that when there is tilting of one of the double images in paralysis, the tilted image does not always correspond to the paralyzed eye. In Case 46, for example, the paralysis was confined to the left eye, and, nevertheless, the patient, when he saw the two images simultaneously, and he compared them together, regarded that formed by the left eye as straight and that formed by the right eye as tilted. That, however, the tilting was really altogether in the image seen by the left eye was clearly shown

by the clinometer. This instrument, in fact, by enabling us to examine either eye separately or both eyes together, furnishes trustworthy evidence as to which eye is the seat of the obliquity.

The Clinometer as a Test for Binocular Metamorphopsia and for the Distortion Produced

by Cylinders.

Except so far as can be gathered from the slight evidences afforded by the cases cited under the heading "Torsion Produced by Ill-fitting Glasses" (see above), I have not yet been able to secure any accurate data as to the usefulness of the clinometer in estimating the degree of metamorphopsia and tilting produced by cylindrical glasses.

To a patient the most striking evidence of the distortion produced by cylindrical glasses is that he sees the sides of a rectangle slope toward each other, so as to intersect the top and bottom of the rectangle at an oblique instead of a right angle. Whether in any given case this sort of distortion is likely to occur or not, I have thought could be determined by the clinometer,* the test being made in the manner already outlined, i. e., by making with the two Maddox rods two intersecting lines of light and rotating the rods until the lines appeared to the patient perpendicular to each other. If his judgments are decidedly and consistently astray, we infer that his estimate of perpendiculars is perverted, and that he will see rectangular objects distorted.

19 persons** were examined in this way. In but two of these was there any possibility of there being a distortion due to glasses. In one (Case 41, already cited), both vertical and horizontal lines appeared tilted 4° or 5° to the right, but both still remained at right angles to each other. In the other case, the use of oblique cylinders appeared to cause a slight torsion of both vertical and horizontal lines, and there was some distortion of a rectangular object seen at close range; but the estimate of perpendiculars, as judged by the clinometer, was not at all abnormal.

In 3 of the remaining cases (Nos. 37, 38, and 43), although there was moderate torsion in one or both eyes, the estimate of perpendiculars was not more than 2° in error, i. e., was practically normal.

In 13 other cases the judgments in this regard were perfectly normal.

In a single case only (No. 44) was there any marked error in the appreciation of right angles; the error in this case being evidently due to the pronounced unilateral torsion present.

The number of cases is much too small to serve as a basis for deductions, except that we may say that the ordinary person, tested in this way, estimates perpendiculars with considerable precision, the error in designating a right angle being seldom as great as 3° and frequently no more than 1° ; and that the presence of faulty torsion, even when unilateral, does not necessarily produce errors in one's judgment of right angles.

The Clinometer as a Test for Scotomata and for Retinal Metamorphopsia.

The clinometer may furnish a ready means of determining the presence of scotomata or of a localized metamorphopsia due to retinal disease, provided the areas of retina involved are not too remote from the macula. For, if the patient looks through the centre of one of the Maddox rods with the affected eye (the other eye being covered), he will see a line of light extending about 20° on either side of the point of fixation. By revolving the rod in its frame, we can make the line of light sweep in a circle, so as to occupy successively all points of the retina about the macula and not situated more than 20° from it. If the line appears interrupted in any part of its length, we should suspect a scotoma, and if it appears curved or otherwise distorted, we should suspect metamorphopsia, the change in either case being due to involvement of a corresponding portion of the retina.

Suppose, for example, that the rod, placed before the right eye, was rotated so that the index H pointed to 30° above the zero mark, and the patient said that a portion of the line near its upper end was blotted out. We would then believe that there was a scotoma in the upper and outer portion of the field corresponding to a defect in the lower and nasal portion of the retina, situated, say, 10° or 15° from the macula. By revolving the line of light still further, and ascertaining when it became whole again, it would be possible to gain an idea of how extensive the scotoma was.

The method would seem to be particularly applicable in the case of ring scotomata.

I have had an opportunity of testing these relations in a single case only,* one, namely, of detachment of the retina. In this case, the behavior of the line of light afforded very good evidence both of the scotoma and of the metamorphopsia produced by the detachment. That is, when the line of light was set vertical, its upper half was cut off altogether and its lower half was inclined considerably to the left. When, on the other hand, the line was set horizontally, its inner half was cut off, while its outer half was not only visible, but also ran undeviated. The situation and character of the detachments were such as to account for these appearances.

Note.—In the course of this paper I have had occasion to use some terms that may require explanation. These are among the terms which I have elsewhere described** and which are used to denote the different movements that the eyes are capable of and which, so far as the torsion movements of the eyes are concerned, are as follows:

Torsion.—A tilting of the vertical meridians of one or both eyes. It comprises:

Intorsion,*** or the tilting of the vertical meridian of either eye inward;

Extorsion,*** a tilting of the vertical meridian of either eye outward;

Later torsion, a tilting of both vertical meridians to one side, i. e., either to the right (*Dextrotorsion*) or to the left (*Laevotorsion*).

*This application of the test I owe to Dr. W. A. Holden.

**Including 3 examined since this paper was presented

*The authors of this review were present at the meeting.

Received 10 February 1993
 Accepted 10 February 1993
 The authors wish to thank Dr. M. J. Madhok for his comments on the manuscript.

Contorsion, tilting of one or both vertical meridians, so that their upper ends converge;

Distorsion, tilting of one or both vertical meridians, so that their upper ends diverge.

By the use of these terms we are enabled to describe in a single word any one of the changes, normal or pathological, that may take place in the torsion movements of the eyeball, and thus avoid a clumsy periphrase.

Additional Use of the Clinometer.

Since the above paper was presented the clinometer has shown itself adapted to the following additional purposes:

First, it may be used to *measure the ability of the eyes to perform torsion movements* so as to overcome slight errors in declination. For this purpose each rod with its index V set at 0° is placed before its respective eye, when the patient will see a blended red and white line. One rod is then rotated until he just begins to see the lines diverge. The amount of rotation of the rod, read off on the scale, will measure the patient's ability to fuse images by performing torsion movements.

It will be readily seen that a similar manœuvre can be employed *to exercise the eyes in performing torsion movements*, just as we use prisms base out both to measure the ability of the eyes for performing convergence and also to exercise the eyes in converging.

Second, the clinometer may be used *to detect simulation of uniocular blindness*. Suppose, for example, the left eye is alleged to be blind. The instrument is placed with one rod before each eye, when the patient will see two lines, one red, the other white, either intersecting at an angle or else parallel and then blended into one. He cannot tell which eye he sees the red line with nor, in fact, whether he does not see both lines with the right eye alone. To still further confuse him in this regard, the rods may be interchanged (by swinging the phorometer bar round), or both lines may be made to appear red by sliding a ruby glass before the white rod, or finally either line may be cut off by shoving a card in front of one rod. The patient who alleges blindness of the left eye is detected if he can be got to admit either that he sees two lines, or simply that he sees the red line formed by the left-hand Maddox rod.

Probably the best procedure is to set both rods vertical, and then, unknown to the patient, slip a red glass before the right-hand rod. The patient will then see a single red line, and, as it is still present, if he slyly shuts the left eye, he will admit that he sees it. The red glass is now slipped a little aside and the left rod is rotated. The patient, who now sees two intersecting lines, one red, the other white, will think the white line is seen by the left eye, and while still admitting that he sees the red line, will probably deny that he sees the white. It is then evident that he is malingering, and the imposition can readily be demonstrated to a bystander, if, leaving the rods in position, we put him in the patient's place.

MEMBRANOUS ENTERITIS ERRONEOUSLY TREATED FOR PHTHISIS—PRESENTATION OF PATIENT.

By J. PRESTON MILLER, M. D.,

Washington, D. C.

Read at the meeting of the District of Columbia Medical Association, held at the Washington Hotel, Washington, D. C., on the 10th day of November, 1901.

This paper will detain you with no learned discourse or bibliographical references, though I confess to having read extensively on the subject, and treated cases with the same malady, before and since, but this one is so unique, and the main disease was so well cloaked that I think the clinical history worthy of report to the society. Evidence as to result of final treatment is presented in the appearance of the patient, who has graciously consented to appear before you.

Mrs. B., act. 35, widow, native of Baltimore, secured a clerical position in the Government Service in 1891, was in good health, weight 150. In the autumn of 1895 she began suffering with severe spells of belching compelling the leaving of her desk to seek seclusion anywhere, often in the water closet, where after a half hour or more continuous eructations of wind she would break out with profuse and exhausting sweat. These spells would sometimes not come for three or four days, then three or four times in a day. The severe attacks were in the evening after dinner, when she often went to bed stripped of all clothing whatsoever because of bloating and hyperesthesia, propped up in bed she would belch until exhausted to such an extent that she would not sleep restfully, sleeping in broken naps. Cold sweats and palpitation of the heart followed every attack from the beginning. Before long asthma supervened also, and in December 1896 she had congestion of the lungs which confined her to bed nearly four weeks. After this, bronchitis, cough, and asthma, were sufficiently abiding to require constant medical treatment. March 4th, 1897, she was with friends watching the inaugural procession from a window for five hours. She suffered much with what she supposed was a distended bladder, but when opportunity came urination brought no relief. Her physician found peritonitis over the cecum, the acute pain requiring frequent hypodermics and opiates internally, for three days. After three weeks she got out of bed and went to Atlantic City to recuperate. On the way she discovered red spots on her hands which had extended up her arms when she arrived at the sea shore: then she had inflammatory rheumatism which kept her in bed three weeks. She resumed her duty in May. In October asthma was so severe she could no longer relieve it with peppermint in water as she had done hitherto. All spells of belching had not been succeeded by asthma, but no asthma came except during or immediately after belching. But now asthma became so severe she would be confined to bed for 10 days or 2 weeks at a time, requiring daily attendance of the physician. Within four months she had three such attacks. The oncoming war in the winter and spring of 1898 required extra time and she worked Sundays and Holidays without ceasing, every day from 9.00 A. M. to 5.00 P. M., then from 7.00 to 11.00 P. M. In October she again broke down, but in a few weeks resumed her duty and continued work until March 1899, when her physician, whose reputation and ability is second to none in Washington, told her she had but one chance for recovery, and that was to quit this climate and live permanently in the mountains. This eminent specialist had treated her larynx and lungs nearly two years and finally told her the bronchial disease had extended beyond reach of medication. Though he did not admit to her she had tuberculosis, his treatment convinced her he believed she had. In June she consulted a well known specialist of pulmonic diseases of Philadelphia, who, having seen her, told her she had but one chance for recovery being permanent residence in the mountains. His treatment consisted of soto and explicit directions to not allow her to expectorate

in vessels, but in cloths which were immediately burned, convinced her of his belief that she had tuberculosis, though he would not tell her so when she asked. Her cough and expectoration were then extraordinarily severe and free, she was using two and three yards daily of soft stuff cut up into expectorating cloths. Friends then prevailed upon her to try a homeopath of Atlantic City who was highly extolled in the treatment of pulmonic diseases. For 5 weeks she grew steadily worse under his treatment, in July and August. She then went to Berkshire Hills, in Massachusetts, where she improved for several weeks, when she returned to Washington, where her cough became severe, and in two days she started for a sanitarium near Atlanta, Ga., in which medicines are not given. Her stomach was washed out daily and she was much massaged and restricted in diet—mostly “whole wheat,” bran bread, scraped beef, etc. The doctor told her she must reside in some mountain of the south, or California, that she could not live long unless she left Washington. The cough having improved she returned home the latter part of November, after having remained in Georgia two months. Neurasthenia had been very marked during the last 16 months, slamming of a door excited violent sneezing and coughing, she had cold sweats night and day, extreme exhaustion on the least movement, and I saw her, later, extend her hands aloft, exclaiming “every bone and muscle in me is so tired it makes me cry. I am so weak I cannot go to sleep,” though she had done nothing more severe than sit up in a chair. January 16, 1900, before dawn I was first called to see this patient. I found her delirious, with a small, rapid fitful pulse, shallow difficult wheezing respiration, requiring a second hypodermic $\frac{1}{4}$ gr. morphia to relieve asthma. Rubefacients, heat and moisture were applied to the thorax for symptoms of congestion, and owing to alarmingly critical symptoms I visited her three times during the day, when threatening symptoms began to abate, my efforts at alimentation and medication were baffled by a stomach which rejected literally everything, though it was washed out daily with stomach tubes. Bromides and iodides for asthma were not born, and even terpin hydrate and heroin for cough in the most agreeable elixirs nauseated and were disappointing in every way. Raw eggs with pepsin and occasionally milk, was the extent of diet for several days. The stomach was washed out daily and every few days minute doses of calomel and enemas were administered for constipation. I sought to destroy pathogenic germs in mouth and stomach by cleansing teeth, mouth, throat and especially tongue with ozonized water composed of hydrozone one part to four of water, used at bedtime and directly after rising. A mixture of hydrozone 1 oz. to sterilized water 1 quart was given in quantities of half glass before food, except when peptonized raw eggs were taken. The frequent nausea and occasional severe vomiting subsided, but the anorexia remained though nux vomica with brandy and various appetizing stomachics were given. There had been no tenesmus, no pain before or during defecation, no abdominal distress below the gastric region, no colicky pain, no shready stools—nothing to suggest membranous colitis. In fact the family and friends were so thoroughly imbued with the belief of tuberculosis that talking against it was in vain. A lover who desired her in marriage came to enquire, and when I assured him there was no tuberculosis he remained incredulous because every doctor who treated her for years prescribed either creosote or permanent abode in the mountains, or both. Her normal weight had been 150, now it was 105. She was possessed with an abiding belief that she had tape worm. Investigation developed no evidence, but she argued “it is the only thing it could be—I have been treated for everything else.” March 16th after santonine and calomel in minute doses for 24 hours I tried pomgranate infusion, but she vomited this and other remedies for tape worm, but finally retained

Ext. Filicis Fl.
Chloroformi āā
M. S. a dose.

3 i

This was followed after four hours by Olei Ricini grms. V in flexible capsules frequently repeated until she passed great masses of shreds which she believed to be tape worms. In a few watery stools retained for investigation I think there was a pint or more of these shreds. They were white and as bizarre as had been the symptoms they produced, resembling mostly strings of rolled dough, or

“noodles,” rolled and bent in all kinds of fantastic shapes. I unrolled some of these and measured one piece which was 18 inches in its greatest diameter. My patient had seen tape worms in the medical museum and found color and other appearances identical with that parasite. I gave specimens for microscopic examination to Dr. J. B. Nichols of this society, who kindly made analysis and reported “mucous enteritis.” As there is such diversity in the treatment it may be of interest to relate mine: Patient tolerated two quarts per enema of normal salt solution, used as hot as she could endure, which she retained five minutes, and immediately repeated, and continued until shreds ceased to come, though this required four, five and sometimes six repetitions followed by introduction of flexible rectal tube, 20 inches long, passed well up into the colon for the injection of one or two ounces of the following: Iodoform 1 drachm, Bismuthii Subnitratiss oz. 1, Olei Amygdalae Dulcis 1 pint. The iodoform and bismuth were increased to double the above amount in the third prescription. The tube was attached to the nozzle of a Davidson syringe, the syringe and tube were filled with the oil before introduction of the tube. By the side of the cup containing the medicine was another containing water, from the latter the syringe drew water after the oil was exhausted to drive home the oil without intermingling of air, the medicine being retained permanently. Before using this oil I had used in the same way solutions of nitrate of silver and gradually withdrew the tube while injecting so as to reach all parts of the colon. This was done two weeks. The oil perhaps six weeks, and after shreds disappeared, and only phlegm remained, I used Fluid Hydrastis. Internally Argenti Nitratis, a grain a day, was given in three doses, an hour or more before meals, combined with 7 or 8 minims of terpinine in capsule. This was alternated every 30 days with tannigen grs. 6 before each meal, giving at the same time olei ricini grms. 5 at bed time. Asthma, cough, anorexia and insomnia had disappeared in a month, and excepting occasional insomnia none of these symptoms have reappeared. Shreds in stools steadily diminished and totally disappeared in ten weeks. Phlegm of almost gelatinous consistence came in great quantities with the shreds but diminished in quantity and density after shreds no longer came and finally ceased to appear in September, and of this there was a slight recurrence with her recent attack of grippe. Neurasthenia, perhaps present in all cases, was very marked in this one, and, as in all my cases, the last symptom to leave except anemia. For this I gave:

Ext. Sumbul	gr. 1
Asafoetida	grs. 11
Mistura Bland	grs. 111
Acidi Arsenosi	gr. 1/30
Strychninae	gr. 1/60
Phosphori	gr. 1/100

M. Fit pil No. 1. S. 3 to 4 pills daily on empty stomach. In anemia, cold sweats, feeble heart, especially with neurasthenia, I know of nothing equally valuable. Mrs. B. suffered for years for want of peaceful sleep, desirable food, ability for outdoor exercise, general good health and appearance, all of which she craved and now enjoys.

Discussion.

In closing the discussion I am painfully conscious of limitations in my ability to answer satisfactorily all interrogatories and criticism made here to-night. I shall address myself here first to what appears to me most difficult in this rare and phenomenal disease; that is, its etiology. While this is admittedly not yet known, the teachings of books, and the faith orthodox of this society as just revealed that it is of psychic or nervous origin, has never appealed to me. The pathology is too gross. The membrane, while resembling a croupous formation, outstrips the latter in thickness and dimensions ten to one, or more, when compared with laryngeal croup. The lumen of the gut is several times as large, and in the colon the membrane may be four feet long, yet croup forms in the larynx and

more knows it has a soul or nerves than do the lower animals. To assert that this croup is neurotic or of psychic origin would seem absurd, and to me the absurdity is infinitely greater when such origin is alleged where a similar membrane is so much larger. I find a suggestion in the anatomy, physiology and histology of the intestines, as to how this membrane may be formed. The small intestine is 20 feet long; the chyme is one and a half to two hours in passing that distance from pylorus to cecum. The colon is four to four and a half feet long from cecum to rectum, and the fecal matter is usually 24 hours in passing over this short distance. Covering the lumen of the intestines and at right angles to its plain there are in every individual about 45,000,000 tubular glands, the principal secreting organs of the intestines—Lieberkuhn's glands. These glands are hollow stems having lengths several times as great in the colon as in the small intestine. These elongated stems become entangled at the free ends like blades of grass in wide shallow lazy streams, and the slow passing of excrement, permits the enmeshing of phlegmy secretions in the colon which in the above simile is not unlike the wold of the sea and the mild eddies of its sluggish tributaries. In this phlegm are microorganisms producing a characteristic material which can be washed out of the colon in quantities of from one to two pints at a sitting. In consistency and general appearance it resembles yeast, producing the crackling noise of yeast when disturbed, though it is more stringy. This is closest of kin to the membrane, being present in many times the quantity and density while the membrane is in the colon, and lingering in diminishing quantity and quality after disappearance of membrane under the best of treatment. Just how oxidation, or deposit of membrane, is formed from this sea-slime—yeast like material, I cannot explain, but that the phlegm causes the membrane I do not doubt. The rarity of membranous enteritis is conceivable when we note the statement of Einhorn, probably the most extensive observer of gastro enteric diseases in this country, who of course treats diseases of stomach and bowel only, and found, among diseases of that class, this disease in less than $\frac{1}{4}$ of one per cent. in the male and slightly more than three per cent. in the female. I desire to express my thanks to the members of the society for the interest manifested in my paper and patient. To Dr. Acker's inquiry as to temperature, respiration, pulse, etc. I can say, none bespoke tuberculosis, but distinctly asthma. When I first saw the patient she had a temperature of 103 with serious symptoms of congestion of the lungs. The temperature rapidly fell, but there remained an afternoon rise of about 1° for perhaps a month. To his observation that membrane did not pass until after I gave calomel. I think it proper to say I do not think that brought away the membrane, for I had often given it before. The first membrane came after tape worm treatment described in my treatment, including oil, cathartics, etc. To the criticism that I uselessly drugged my patient and that she would have gotten well as quickly without drugs, I beg to submit she had received abundant no-drug treatment. Institutional in Georgia, sea-side in New Jersey, and mountain in Massachusetts.

as reported in my paper. I desire especially to thank Dr. Adams for having kindly made the physical examination of the patient this evening and reported the result to you. He has elicited information from her which I did not possess, viz., that the eminent Philadelphia physician referred to in my paper examined her sputa and stools microscopically, but did not report to her his findings, the latter very naturally. I beg to remind you it was he who had all her expectoration cloths immediately burned, and in his private sanitarium forbade her to expectorate in any vessel. Among my critics I was astonished at being told by a doctor that I could not pass a tube above the sigmoid flexure, and find still more remarkable his statement that he served as interne in a hospital where it was perfectly well understood that no tube can be passed up into the colon. In private practice I do not find this a difficult feat, and in a recent post-graduate course in New York at the Polyclinic various methods of passing above the sigmoid were demonstrated, and sometimes a half-dozen times in a day on patients before the class. I teach my patients how to pass the tube by showing them about how far the flexure is within, and instruct them to press the bulb of the Davidson syringe once or twice if they meet with resistance at expected distance, and thus make the fluid force the way for the tube, which must be promptly pushed after the contents of the syringe. The tube which I used in this case was 20 inches long, and I passed it full length; if it had turned as the doctor says all tubes do, its point would have followed the line of least resistance down by the side of the stem of the tube, the point projecting two to four inches from the anus. If retained within the rectum the injection would have surely escaped or told on the tube when withdrawn, neither of which ever happened.

THE KNEE-JERKS IN CHOREA.*

By AUGUSTUS A. ESHNER, M. D.,

of Philadelphia.

Professor of Clinical Medicine in the Philadelphia Dispensary; President of the Philadelphia Hospital Association; Physician to the Philadelphia Orthopedic Hospital; and Lecturer for Nurses in the St. Elmo.

While ordinarily easy, the diagnosis of chorea is occasionally attended with not inconsiderable difficulty, and it would be a great advantage did we possess some distinctive symptom upon which dependence could be constantly placed. The two conditions most likely to be mistaken for chorea are spasmodic tic and the athetoid movements attending various cerebral lesions. The differential features are briefly as follows:

Chorea is a self-limited disease, probably of infectious origin, although there may be relapses and recurrences. Spasmodic tic is of uncertain or indefinite duration, and results especially from reflex influences, from habit or imitation or without obvious cause. Athetosis also may persist indefinitely and, as indicated, is usually the expression of some cerebral lesion. The movements of chorea may be described as involuntary, irregular, jerky, incoordinate and purposeless. They may begin in one member and extend to the other member of the same side,

to which they may remain confined; or they may extend successively to members of the opposite side. Commonly, the movements preponderate upon one side, and there is often associated weakness of the affected part. The movements of spasmodic tic, on the other hand, appear coordinate, purposive and repetitive. They are generally local, often disappearing from one situation to appear in another. Athetoid movements also are involuntary and incoordinate and peculiarly vermicular. They are usually confined to the same member or members, and are associated with paralysis or paresis, as well as other spastic phenomena and mental deficiency. The knee-jerks are unchanged in cases of spasmodic tic and exaggerated in those of athetosis, while in cases of chorea they are extremely variable in different cases and even in the same case at different times, being sometimes increased and sometimes enfeebled or wholly wanting.

Gordon (*British Medical Journal*, March 30, 1901, p. 765) has called attention to a peculiar modification of the knee-jerk, which he believes to be common in cases of chorea. In his experience it is not constant, but when present it is considered distinctive. Gordon states that with the patient recumbent and the knee raised, while the heel rests on the couch and the muscles of the extremities are relaxed, if the patellar tendon be struck, the foot rises, but instead of falling back immediately, it remains suspended for a variable time, then sinking back slowly to its original position. Sometimes it is said there is merely a sluggish descent following an ordinary ascent. Sometimes there is the ordinary knee-jerk, but as the foot is beginning to descend it is caught in midair and held for a time or is even raised to a higher level than was reached in the first jerk. Sometimes the knee-jerk passes at once into active, more or less persistent—even apparently voluntary—rigid extension of the extremity.

The phenomenon is said to be best observable in mild cases, because in them it is not interfered with by the frequent and extensive movements of severe cases. In cases of hemichorea, it is said to appear only upon the affected side.

The opinion is expressed that the manifestations noted are due to an additional involuntary movement evoked by the knee-jerk. The choreic movements themselves are attributed to an overflow of impulses evolved for the purposes of ordinary voluntary activity. In support of this proposition the following test is proposed:

If a patient with suspected chorea raises both arms vertically with the hands held open, there may or may not be slight occasional choreic movement of the thumbs or fingers, or both. If now the tongue is protruding, existing movements in the thumb and fingers are intensified, or if not previously present are evoked.

The explanation offered for this phenomenon is that impulses in one set of centers necessary to induce voluntary movement overflow or are conveyed to neighboring centers and give rise to involuntary movement. The peculiarity of the knee-jerk described is thought to support this hypothesis of the mechanism of the movements of chorea.

I have repeated the observations of Gordon on the knee-jerk in a small number of cases, and am

able in part to verify his statements with reference thereto. The phenomena are not elicitable in every case. When present they seem to represent an intensification or a reenforcement, or in some instances to act as an excitant, of the choreic movements. Thus, in a colored child with mixed blood, seven years old, in a third attack of chorea with physical signs of endocarditis and valvular disease the tap on the patellar tendon, with the patient in the recumbent posture and the knee raised, was sometimes followed, not only by the double jerk, or a belated single jerk on the side struck, but also by palpable and visible contraction of the hamstring muscles with flexion of the leg, sometimes at once, at other times after a little delay. The blow on the tendon seemed further to set up a series of movements also upon the opposite side as well as in other parts of the body.

HEREDITY AS A FACTOR IN MENTAL DEFICIENCY.

By T. ALEXANDER MAC NICHOLL, M. D.,

OF NEW YORK.

Were men as careful in laying the foundations for a good posterity as they are of maintaining the lineage of a horse or the blood of a barnyard fowl, such a human monstrosity as the 16-year-old murderer executed in Connecticut last July would become an impossibility. This lad, held in the hereditary clutch of two or more generations of depraved ancestors, started life a moral pervert, cruel and remorseless. His father was weak-minded and a drunkard; his father's brother was an epileptic; his mother was feeble-minded, a prostitute, and died drunk in the street; his mother's sisters were all drunkards; his mother's brother died insane; his paternal grandfather was an epileptic; his maternal grandfather died insane; his maternal grandmother was an epileptic, a drunkard, and a prostitute.

Heredity prepares the soil and implants the tendencies; environment may modify them.

Devitalize the system in one or through successive generations, and the sum total is mental deficiency, loss of organic integrity, dipsomania, epilepsy and other psychoses.

Reformatory, prison, and asylum are pictorial volumes of the potency of hereditary taint in producing a degenerated offspring.

In no less unmistakable a manner does mental deficiency point to a defective origin. This is evidenced by the results of an investigation conducted by the writer for the purpose of determining the bearing of heredity upon dullness. Despite the difficulties attending such an investigation, we have secured data of 10,000 children.

Of this number, 885, or 8.8% showed more or less marked mental deficiency. The dullness of 40 is reported as due to environment and physical conditions, in which are included poverty, defective sight, deafness, and general constitutional weakness; 221 are classified as due to heredity; 471 others as children of drinking parents; of the remaining 153, no definite information was procured. The children examined, with few exceptions, had good hygienic surroundings, many of them had defective eyesight

*Presented to the Academy of Medicine, N. Y. City, April 18, 1901.

corrected, difficulties of hearing removed, and other physical infirmities improved, but the mental deficiency remained; a distress to the parent and a constant irritation to the teacher. A few were placed under trained private teachers, but the progress was far from ideal, and the children returned to school; others who were given work in manual training schools developed much mechanical ingenuity, but showed little other mental improvement.

Those conditions which impair the integrity of nerve tissues or profoundly affect nutrition, are the active agents in the preparation for the transmission of hereditary ills.

We have been able to trace the family histories of 463 children in 150 different families, through three generations. 17 (2 males and 15 females) were precocious in some one thing, as music, drawing, etc. 403 were generally deficient (193 males and 210 females); 17 had neurotic fathers; 78 neurotic mothers. 313 had drinking fathers; 51 drinking mothers; 43 had neurotic grandparents; 265 had drinking grandparents; 246 had drinking parents and grandparents. 2% of these children had parents of less than average intelligence. A most notable fact in these families was the constant relation of alcohol in the ancestry to abnormal physical conditions in the descendants. While 87% of these children of drinking and neurotic ancestry were mentally deficient, 76% suffered from some neurosis or organic disease.

The contrast between these and abstaining households is very striking. I give you the results of a study of 51 families of 231 children having total abstinence antecedents. Of these, less than 3% were dull, and but 18% suffered from any neurosis or organic disease.

Such facts as these stamp heredity as a most important factor in mental deficiency, and alcohol as a most active agent in the production of hereditary degenerations.

The records of the following three classes of parents and their families would be of more than passing interest in this connection. A study of 24 families of drunken parents shows 113 children, of whom 93 had organic diseases, 66 mentally deficient, 7 idiots, 8 dwarfs, 7 epileptics, and 16 drunkards.

76 families of moderate drinkers had 236 children, of whom 186 had organic diseases, 169 mentally deficient, 8 idiots, 8 insane, and 21 drunkards.

31 families having neither neurotic nor drinking ancestry, had 116 children; 20 had organic diseases, 3 mentally deficient, 1 a drunkard.

In other words, while the children of drinking parents show less than 12% normal in mind and body the children of total abstainers show over 82% normals. Thus the families of drink imbibers in large measure augment the number of drunken, diseased and defective members of society.

Wealth and social environment cannot always overcome misdirected biogenetic forces, as illustrated in the following family history:

A moderate drinker of good, sturdy inheritance married an equally healthy woman, an abstainer; the result of this marriage was a son of strong physique. The father died of cerebral hemorrhage at the age of 34; the mother died of lung trouble at the age of 70. The son became a moderate drinker,

married a moderate drinker, descendant of a vigorous stock, and died of cerebral hemorrhage at the age of 70. The result of this marriage was one son and two daughters; one of the daughters, unmarried, died of cancer; the other married a moderate drinker. Two precocious daughters were the result of this union. The son, a heavy drinker, married and raised a family of one boy and one girl. The boy, in spite of wealth and the severe discipline of a military school, is vicious and mentally deficient, while the girl is an imbecile.

It is self-evident that any treatment of mental deficiency which disregards cause must fail of permanent results. Segregation of at least 90% of these pupils in special classes under well equipped teachers, aside from the lifelong stigma such segregation entails upon child and parent, will at best conceal the grosser manifestations of the evil while the cause remains.

The child's first claim upon the State is not education, not liberty, not even happiness; but it is life, it is health. No human agent should have any right to the indiscriminate dispensing of that which contaminates the fountain head of citizenship, implants disease in the offspring, and casts upon the community an unnecessary burden of defective and degenerate youth.

Let the State interdict the sale of alcohol as it does other narcotics, and prevent or control the marriage of the mentally deranged with healthy members of society, and not only crime and insanity will diminish, but there will be a rapid reduction of mentally deficient children.

The youth who, in spite of a vicious environment, makes of himself a man, thoroughly furnished unto good works, merits our praise; but he who, cast in a defective mould, starts life in the implacable grasp of poverty and vice, demands our sincerest sympathy and our wisest thought.

Malaria and the Sanitation of Malarial Regions in Corsica.—Pitti-Ferrandi (*Ann. Hyg. et de M. et de Ch. p.* April 14, 1901. 48me. Année, No. 30). (Paris Thesis, 1900-1901, No. 206). Malaria is very frequent in Corsica. In order to prevent the further development of the disease Pitti-Ferrandi believes that a number of free stations for the distribution of quinin should be established in the malarial regions, that the government should supply the inhabitants with mosquito-nets and frames, and that the immediate application of new discoveries concerning the use of petroleum should be made. In general, the mosquitoes and their larvae should be destroyed by all known means. Potable water should be introduced and stations for the distribution of mineral water should be established in the swampy plains. The planting upon a large scale of the eucalyptus tree and the retimbering of the mountains, the re-establishment of the penitentiary of Casabiana and the establishment at other points of practical schools of agriculture or other agricultural institutions are further means of combating this disease. [J. M. S.]

Aspirin in Pleurisy with Effusion.—N. A. Savelieff (*Medicinskoje Obosrenie*, April, 1901) employs aspirin in cases in which salicylic acid or salicylate of soda is indicated, with exceptionally good results. The untoward effects of the latter are as a rule absent when aspirin is used. In one case of pleurisy this drug rendered valuable services by reducing the temperature, producing profuse diaphoresis and diuresis with consequent diminution of the effusion. The only objection to the drug is the high price. The author reports also a case of idiosyncrasy towards the drug. A woman suffering from rheumatism took 5 grms of aspirin in fractional doses. On the second day ringing in the ears, weakness and delirium developed. [A. R.]

The Surgical Treatment of Epilepsy.—We recall very well the wave of enthusiasm which swept over the professional world about thirteen years ago with reference to the surgical treatment of focal epilepsy. In 1888 Dr. David Ferrier and Mr. Victor Horsley were in this country, and when they visited Philadelphia were taken to Blockley (which Hospital one of them compared with the Salpêtrière for wealth of clinical neurology) and were there shown some of the results obtained in the very earliest work in local cerebral surgery in America. The names of the distinguished visitors were names to conjure with in cortical topography, and it is not to be wondered at that their visit strongly stimulated the new-born zeal for trephining every available case of epilepsy. The enthusiasm of those days was felt all over the medical world, and led to an immense amount of operating; and thus it has happened that that enthusiasm has since been tempered with much and even bitter experience. As in the case of all extreme movements, this one has suffered from a powerful reaction, until it has almost come to the pass that the neurologists and the surgeons who resort to trephining in Jacksonian epilepsy are obliged to assume an apologetic tone. This, perhaps, has been inevitable, but it should not be always so. We are convinced that the operation in certain selected cases is a useful one, and that the time has come when the judicial opinions of expert neurologists and conservative surgeons can be counted on to favor a cautious propaganda of this faith.

We publish in this number of the *Journal* two papers which are contributions of this sort. Dr. Putnam is not one who looks for practical results through rose-colored glasses. His paper can be read with the confident belief that it embodies sober and mature reflections. On Dr. White's paper special comment is called for from the fact that it contains a bold and entirely original suggestion. The topical treatment of focal epilepsy has heretofore been pursued by the excision of the offending centers; this was a surgical treatment that was especially popular with medical men. But Dr. White's topical treatment, although suggested by a surgeon, is es-

entially a medical one, for it consists in injecting a solution of eucaine into and beneath the cerebral cortex. In other words, it depends upon the action of a drug, and the only surgical element in it is the slight operation necessary for applying this medicament. It is, perhaps, too early to appraise this treatment at its true value, and it is noteworthy that Dr. White himself is exceedingly conservative and properly cautious in recommending it to the profession. It lends itself easily to speculation, especially as to a possible antidotal action upon a theoretical toxin. Can it be assumed, if this treatment is found to lead to a measure of permanent success, that it antagonizes the action of an auto-genous poison or of an invading microbe? Or does it act by impressing nutrition in some unknown way? The cytoplasm of a neuron, we could suppose, might retain the impress of a powerful agent thus introduced, so as to present permanently, or at least for a long time, new combinations in its biochemistry. Only by some such theoretical suggestions could the treatment be explained. But empirically we do not need that a treatment should be categorically explained, and Dr. White's suggestion opens up quite a field for cautious experimentation not only with eucaine, but possibly with other drugs.

The Meeting at St. Paul.—The annual meeting of the American Medical Association should always be of such importance as to be an object of interest and instruction to every medical man in the United States. The session just held at St. Paul was of special interest and of historical importance because the Association succeeded in reorganizing itself. This was a most significant feat, for it is one which has failed of accomplishment several times heretofore largely for lack of time. This reorganization was absolutely essential as a preliminary to a successful career for the Association as a real representative national gathering. Before this was accomplished it could scarcely be said that the Association did or could properly represent anything but itself. In fact, it was simply a huge medical society. It is now constituted with a House of Delegates, which represents the State Societies and by

them the general profession, and which has a definite, determinative and effective organization. This Chamber can represent a policy, pursue a course, transact a measure, and attend to business in a way that was formerly impossible in the loosely organized association at large. If there is any virtue or force in representative government (and who doubts that there is?) the Association will now reap the benefits. It is in a position as never before to influence public opinion and to act upon legislation, but its best friends should not forget that only that form of government "which is best administered is best." The new House of Delegates can soon sink to the level of some of the State Legislatures if it is run in the same way.

It is rather too early to judge of the literary and scientific quality of the meeting. It will be time enough to do that when the original papers are put into cold type. These papers, however, were evidently of very uneven merit, as is apt to be the case in a large and miscellaneous gathering. Perhaps one of the functions of the new House of Delegates will be to keep a jealous eye open for a high standard of scientific work.

The Association put itself squarely on record in favor of some common sense legislation, and declined to make a declaration on the subject of military morality in the Philippines when importuned to do so by some elderly parties who probably were not very well informed on this delicate subject.

The revision of the code of ethics was not favored by the majority present and was voted down. This will please the conservative members of the profession everywhere, but will probably not discourage the revisionists, who seem to be in an eternal mood of hopefulness and determination.

From the social and personal standpoint, the meeting seems to have been fairly successful. We have heard some complaints about lack of accommodations and about the great distances that separated the meeting places of the various sections. Such things, we suppose, are inevitable when the meetings are largely attended and are held in smaller cities and towns. The city of St. Paul distinguished itself for courtesy to the strangers within its gates.

The Relation of the Physician to Legislative Affairs.—The President's address, delivered by Dr. Charles A. L. Reed, before the American Medical Association at its fifty-second annual meeting, contains much that is of value to the American medical profession concerning its relation to state and national policy. It is an unfortunate but no less a well-known fact that the medical profession as a body in the United States has too little influence;

in all probability, because it lacks efficient organization and capable leadership. Dr. Reed points out that this lack of solidarity was the cause of the degradation of the army medical corps, and of the unfair and humiliating discrimination against the men who compose that most necessary arm of the service.

The present law grades the medical department for rank, promotion and pay far below every other department and special corps of the army, and, with the exception of second lieutenants, it also is graded below the line.

The status of the physician in the army seems to be similar to his position in civil life. The sick and wounded demand the time, attention, and superior knowledge of the physician, but when the wound is healed and the lost health regained, the beneficiaries often wish to cut down the remuneration for services rendered to the least possible figure. As Dr. Reed properly says: "Physicians are citizens of the Republic. As such they are intellectually, socially, politically and officially the equal of any other element of the body politic. There is no station to which they may not attain; there is no distinction of which they may not be the recipients. They are, in very fact, peers of the realm and peers of any peers of any realm."

Let us reorganize the American Medical Association so that it shall have a leader who shall be in a position to make its influence effective, and a legislative body to whose acts every member of the profession will adhere loyally. In electing the man who shall be the executive head of this body, let each member of the profession cast his vote intelligently, and when the count is made, let the minority abide by the decision of the majority. Let there be no selfish politics in our campaigns, but rather let us be broad-minded, remembering that truth and justice cannot be found coincident with the ideas of one group alone. Then let us raise the standard of requirements for entrance to the study of medicine and for graduation. Give the young men the best instruction possible, and require that they shall show evidence of having profited by that instruction. Then shall we have a profession, the members of which will stand shoulder to shoulder and push the physician into the front rank of intellectual and scientific attainment and influence. Let us regard the example set by France, to which we make editorial reference. Dr. Reed's address was admirable in every respect, and especially in its timely discussion of problems that are of vital importance to the medical profession in this country.

The Doctor in Politics.—The *British Medical Journal* publishes a list of the medical men who are

members of the French Parliament. From this we learn, much to our enlightenment, that no less than 42 physicians are members of the French Senate, and no less than 53 are in the Chamber of Deputies. We think these numbers will surprise most of our readers on this side of the Atlantic, as they have surprised us. These medical members of the French Legislature form an important Parliamentary group, which, by its size and the united influence of its members, is able to effect legislation in many ways. This group is regularly organized, and Professor Cornil, Senator for Allier, is chairman of it. Cornil has taken a leading part in medical and sanitary legislation. Professor Labbé was a foremost promoter of the medical reform bill; Dr. Pedebidou has championed the cause of underpaid doctors in the public service; M. Dubuesson has agitated the amendment of the law relative to accidents, and M. Dron has procured the removal of the tax on physicians' carriages as objects of luxury. These are only a few samples of what can be done.

In this country, unfortunately, there is a sort of prejudice against the doctor going into politics, and a more irrational prejudice was never conceived. We have especial need in America for the services of well-trained physicians in the legislative services. This is, perhaps, especially true in municipal affairs, but it is also true in State Legislatures and in Congress itself. If there were as large a proportion of well-educated physicians in Congress as there are in the French Parliament, we might secure some much-needed legislation in this country, and might avoid some that could well be spared. One difficulty with us is to induce the better men to run for such offices. A political canvass often entails loss of practice, and, to some extent, loss of prestige—but this latter, at least, should never be so. They do these things better in France.

The Army Canteen.—No one need be surprised that the effects of the law abolishing the canteen from the United States Army are proving disastrous. No man with average worldly sense, who knows that soldiers should be treated like men and not like school boys, need hesitate to raise his voice in protest. The action of Congress, in the first place, was doubtless insincere, for it was largely in response to the agitation of a woman's temperance organization, and was evidently not in accord with the personal convictions of most of the Congressmen who voted for it. The attempt to make men total abstainers by act of Congress will fail, as it deserves to fail. The willingness to indulge the impractical ethics of a private organization of agitators at the expense of the comforts and personal rights of the soldiers in the United States Army,

will evidently soon be rebuked by an enlightened public opinion. During the short time that the law has been in force, it has led to increase in drunkenness and, worse yet, to increase in venereal diseases. Dr. L. L. Seaman, in a paper read before the Association of Military and Naval Surgeons, quoted in the *New York Sun*, openly declares this to be a fact. The men who are obliged to leave the post for the saloon, find it a short step evidently from the saloon to the brothel. The American Medical Association at St. Paul has put itself on record in a resolution in which it deplores the action of Congress in abolishing the army post exchange, or canteen, and in the interest of discipline, morality and sanitation, recommends its re-establishment at the earliest possible date.

The effect of the act, as we understand it, is to deprive the soldier of his social club and a part of his social life within the precincts of his post or garrison. If such a law is to stand, we should all look out lest every club in civil life be closed ere long by some more of this grandmotherly legislation.

The Oldest Printed Medical Book.—Dr. Frederick P. Henry, the Honorary Librarian of the College of Physicians of Philadelphia, has the true scholar's instinct to range himself among the *laudatores temporis acti*. In a recent address delivered before the Book and Journal Club of the Medical and Chirurgical Faculty of Maryland (*Maryland Medical Journal*, June, 1901), Dr. Henry started to describe the valuable collection of Incunabula in the College Library, but he became so much interested in one of these old books that he very wisely decided to devote himself to a description of it alone. To this fact we owe his most interesting account of a volume which he tells us is reputed to be the first printed medical book. This is the *Tractatus de Epidemia et Peste*, of Valescus de Tarenta. About this rare and venerable tome, which is one of the priceless relics of primitive typography, Dr. Henry discourses in a most instructive way. This book was printed doubtless before 1474, but, like the very oldest incunabula, it is without date, and the proof of its age is collateral. Its contents are appropriate to the present time, for it discusses the Plague (that perennial subject in medical literature), and, as Dr. Henry tells us, it is redolent of the past, for it contains the ancient prescription called the "theriaca," which was composed of sixty or seventy ingredients. The "Incunabula" are the books that were printed before the beginning of the Sixteenth Century, and Dr. Henry has done well to introduce the patriarch of the bibliological fold to a modern and somewhat forgetful medical public. Valescus

de Tarenta was a Portuguese physician, who seems to have taught in the ancient university of Montpellier, and who wrote his book many years before the invention of printing. He never saw the child of his brain in print, and would doubtless have been much surprised if he could have known that it was to be distinguished in future ages by being numbered in a favored class called the Incunabula.

Retrospect and Prophecy.—In his able résumé of the advances made in internal medicine, in the 19th century, Dr. N. S. Davis, Jr., in the annual address before the American Medical Association, has touched at the end, upon the part which is, perhaps, most interesting to us all, namely, the probable advancement that will take place in the present century.

Prophecy is an art easily learned. To acquire it one needs as capital, assurance and imagination, added to a more or less intimate acquaintance with the past. With these it is possible (for such is the credulity of the world) to acquire a large and devoted following. Nevertheless, the perusal of Dr. Davis' article has inspired us to attempt to go a little further than he has gone.

It is trite to mention that stagnation never occurs. Things go forward or backward. For instance, there is no question, since the discovery of elaborate surgical instruments at Pompeii, that operations were then performed whose very memory has been lost. And we must believe that at that time surgery had advanced to a point of considerable efficiency. Then it retrograded with the fall of Rome, and even during the Italian Renaissance was probably less advanced than at the beginning of the Christian era. From that time it advanced slowly, indeed almost imperceptibly. Then came the French Revolution, and to the terrific stimulus to human activity produced by it, medicine was at once the debtor. It was to this era that Corvisart, Bichat, and Laënnec belonged, who founded the sciences of diagnosis and pathology, which were and are inseparable. In the vast industrial development that has followed the increased facility of communication, human activity has again been stimulated to the utmost, perhaps, over-stimulated. And, according as it will continue to develop or commence to retrograde, two courses are possible for medicine. Either it will stop at or near its present point, seemingly on the threshold of great discoveries; or it will advance, the discoveries will be made, and our descendants will reap the reward perhaps in the extirpation of infectious processes, and a knowledge of human physiology that will render possible almost continuous health. Let us look for a moment on the pessimistic side. As in all periods of retro-

gression, exact observation will gradually cease. In its place meaningless terms, the most extravagant theories will occupy the attention of physicians, who will have numerous cults and sects. Methods which we now regard as arrant quackery will flourish among the most distinguished of the profession. Medical morality will be impaired, and instead of cultivating hygiene and prevention, the profession will, at least negatively, encourage the increase of the disease. And the work that advancing science is beginning to regard as useless will be done over and over again in a routine manner, and obtain much applause. There is a certain amount of justification for this gloomy picture, for the condition of the world, the unrest of the masses, the concentration of wealth in the hands of the few, is not unlike that which commenced in the last days of the Roman Republic, continued during the Empire, and gradually wrought disaster.

On the other hand, we can hope that Dr. Davis' view is correct. That methods of investigation as little dreamed of as was the Röntgen ray, will be discovered; that the medical profession will awake to the importance of pharmacology and therapeutics, and no longer allow them to wither in neglect, and that our medical grandchildren will regard us as quite as hopelessly, almost wilfully, ignorant, as we regard our medical great-grand-sires.

Gastroptosis.—Gastroptosis, or Glenard's Disease, is one of the most complicated in medicine. In the first place, it seems quite certain nowadays that this condition is not really due to the causes that were originally supposed to produce it, that is, tight lacing, repeated pregnancy, etc., for it is by no means uncommon in men. In the second place, although it is often associated with the gastro-intestinal type of neurasthenia, not infrequently with hypochlorhydria and constipation, and a moderate degree of anemia, it is not so very rarely found in persons whose health and nutrition leave nothing to be desired, and in all likelihood would be more frequently found if more frequently sought. For, as a matter of fact, the position of the stomach is rarely determined with much accuracy, except in persons suffering from obvious disturbance of that organ. Nevertheless, gastroptosis, or more accurately speaking, splanchnoptosis, is an abnormal condition of the abdominal viscera. Various methods have been devised by which reposition may be affected. Among the most drastic of these is the operation of Beyeau, which consists of stitching the stomach to the diaphragm. As this can be employed in only an excessively small proportion of the cases (as a matter of fact, we believe there is only one such attempt on record), the majority of physicians will

prefer some external support applied to the abdominal wall. For this purpose a number of binders have been devised, but they all have the disadvantage of having a tendency to slip upward, under which circumstances they are more apt to depress than support the organs. To obviate this an ingenious method has been devised by Lincoln (*The Medical News*, Sept. 1st, 1900), who employs straps of rubber adhesive plaster cut in a peculiar way, the broader portions being attached to the ventral surface and the narrow portions crossing in the back. By this means the binder remains fixed in one position, supports the lower portion of the abdomen, and usually gives more or less relief, or at the very least, an agreeable sensation of support. Such mechanical methods can at least do no harm, and if they accomplish nothing more than the encouragement of the patient, are well worth a trial.

A Liberal Education and the Study of Medicine.

—The *Outlook* has recently published a laudatory notice of the utterances of Dr. Edmund W. Holmes, of this city, in respect to a liberal education for professional men, especially medical men. Dr. Holmes has analyzed the figures supplied by a number of American universities, and finds in some of them, especially those which are noted for their medical curriculum, a distinct tendency away from what is usually called a "liberal education." He attributes this tendency to three principal causes. First, the desire to begin professional work early. Second, the encouragement of the belief, held by some professional men, that a college education is a waste of time. Third, the popular error that a professional or technical education is of itself a liberal education. Dr. Holmes does not agree with these views, and we agree with Dr. Holmes. We have never sympathized with the opinions of those medical teachers who are constantly declaiming against a liberal education for the medical student. We understand fully the grounds upon which they base their objections. It is, if we mistake not, the utilitarian objection that a liberal education is not necessary to success in the practice of medicine. We do not attempt to combat this statement. We know that it is in large part true. It is easy to point to very many men who have been eminent in our profession without the assistance of a liberal education. We grant this without dispute, and we honor these men not the less, but rather the more. We think, however, that the argument is doubly fallacious and unreliable, and that in fact it has nothing whatever to do with the real question. A liberal education is not intended for mere utilitarian advantages. One might as well speak against the fine arts, or literature, or ethics, or even against religion itself, because these are not absolutely essential to a techni-

cal training, as to decry a liberal education. Such an education is not intended to be a mere aid in the winning of bread and butter, neither is it intended to be a mere accessory to a technical training, although we believe the time is coming when it will be more and more a necessity for success in some of the purely technical pursuits. But, laying that aside, it can be broadly stated that a liberal education has an entirely different object, and that that object is the cultivation of the mind, the broadening of the intellect, the endowment of the moral sense, the acquaintance with the best attainments, history, cultivation, literature, and development of the race, and that it is far above all considerations of mere utilitarianism.

The case of Huxley is well in point. This eminent man suffered from the deficiencies of his early education, but he realized this so fully, and devoted himself so assiduously and so successfully to the remedy of these defects, that he became a man of wide cultivation, not only in science, but in literature, languages, philosophy, metaphysics, history, and even theology, to all of which he added the advantages of a fine literary style. Was this liberal education of no advantage to Huxley?

With respect to medicine, which is a profession that brings a man most intimately into contact with his fellows, we believe that from a mere personal standpoint, a liberal education is a desirable and appropriate thing for a physician to have. We do not contend for a moment, however, that it is a necessity for his success or profit. We think it should be apparent, nevertheless, to most thoughtful observers that the argument that a young man cannot spare the time to be liberally educated is a most unconvincing one. It makes practically little difference to his success whether a young man receives his medical degree at twenty-two or twenty-three, on the one hand, or twenty-five or twenty-six years of age, on the other. If there is any advantage it is on the side of his not taking his degree too early. Few men succeed in the practice of medicine until they are well past thirty, and the years before thirty can well be devoted to education in the widest sense of that word. A young man has lost nothing who has given a few additional years to the cultivation of his mind. Such a curriculum certainly does not disable him for anything, while as a rule it not only makes him more readily efficient as a student of the intricate sciences of medicine, but it gives him a personal endowment which is of inestimable advantage to him as an individual and a citizen. The claim that a young man wastes three or four years of his life in the cultivation of his mind in attaining a liberal education can only be based upon an erroneous view of what constitutes one of the highest aims in life.

Reviews.

"The History of Medicine in the United States.—A collection of Facts and Documents Relating to the History of Science in This Country, From the Earliest Colonization to the Year 1800; with a Supplemental Chapter on the Discovery of Anesthesia," by Francis Randolph Packard, M. D. Philadelphia and London: J. B. Lipincott Company, 1901.

Those who have read the interesting articles from the pen of Francis R. Packard on various subjects relating to the early history of medicine can imagine the value of this volume, and can appreciate the author's peculiar fitness for the work which he has undertaken. The author displays too great modesty when he describes his work as a "collection of facts and documents relating to the history of medical science in this country," for although this in some degree describes the work, yet these facts and documents are so placed in their relation to one another and with such entertaining comments and paragraphs by the author, that it would seem to us that the simple word history would best describe what is to be found between the covers of this interesting volume. Not only will the reader find this work pleasing and entertaining, but it will also serve a most excellent purpose as a book of reference, being filled as it is with such accurate accounts and notes regarding the histories of medical men, of epidemic diseases, hospitals, medical societies, etc., during the colonial period and the early part of our national life.

The book is composed of 11 chapters and 5 appendices. The illustrations are particularly interesting and many of them are produced for the first time. The thoroughness of the work extends through the index, which will be found most satisfactory by those wishing to refer to any of the subjects treated in the text.

Chapter I relates the medical events connected with the early history of the English colonies in America. In it are to be found many amusing and entertaining accounts of the medical treatment received by the early colonists. Chapters II and III refers to the history of the various epidemic sicknesses which were prevalent from the earliest colonization to the year 1800. Here the author gives an interesting account of the use of inoculation with smallpox, and of the trouble which its early advocate, Dr. Zabdiel Boylston, suffered at the hands of those who were opposed to this method of prevention of smallpox. It was not long, however, before this practice became very popular, many prominent men, among whom was Benjamin Franklin, having undergone the most radical change regarding their attitude toward it. So prevalent did this treatment become that inoculation developed into a specialty and houses were especially set aside for the care of those undergoing the treatment. The introduction of vaccination into the United States is ascribed to Dr. Benjamin Waterhouse, who in 1800 obtained some vaccine virus from England and vaccinated his own son.

The terror and ravages of yellow fever epidemics so frequent in the early days, and the various methods of their prevention and control are interestingly related, particularly the experience of Philadelphia with this disease. In this connection the author has introduced a number of interesting anecdotes regarding the controversies in relation to the treatment of yellow fever, which were indulged in by the adherents of Dr. Rush on one side and of Dr. Kuhn on the other. These disputes at the time so acrimonious now afford the reader only amusement. Canings, duellings and lawsuits were quite common among medical men at this time.

The courage and adherence to duty displayed by the medical men of Philadelphia at this time is shown by the fact that many lost their lives by remaining in the city and attending to the stricken at a time when everybody who could afford it went to the country.

Chapter IV deals with medical education before the foundation of medical schools in this country. This chapter is illustrated by the reproduction of a number of interesting certificates granted students by their preceptors. Many American students went abroad at this time to complete their education, and Packard has reproduced some of the tickets issued by the hospitals and universities admit-

ting students to the lecture and clinics, and it is amusing to find there permits printed on the back of playing-cards.

The first medical degree in this country was conferred by Yale on Daniel Turner in 1720. This, however, was an honorary degree. Packard thinks the first degree conferred after a course of medical study was that of John Archer, from the College of Philadelphia in 1768. The first law regulating the practice of physic was passed by the Virginia Assembly in 1736. Philadelphia seems to have been the center in these early days for medical teaching, and Packard goes very thoroughly into the history of this time. The part taken by the Pennsylvania Hospital in the education of students of medicine is carefully reviewed in this chapter. An interesting figure in the medical world at this time was Dr. Abraham Choquet, of whom many amusing stories are related, and a reproduction of a wax medallion made "by his servant, Dr. Eckhout" inserted as an illustration. Chapter V deals with the early medical schools, the first of which was the University of Pennsylvania, and the second the College of Physicians and Surgeons of New York. Anyone interested in military medicine will find Chapter VI full of entertainment, for here the author in a pleasing style has gone deeply into the medical men and methods of the Continental Army. Those who suffered unjust criticism and abuse during our recent war with Spain will find comfort in these pages. In Chapter VII the early hospitals are discussed, and the Pennsylvania Hospital, which is the oldest institution of the kind in America, is allowed a number of pages in which are described briefly but entertainingly its origin, progress and its benefits both to suffering humanity and to the medical profession. The improvement in the treatment of the insane in this institution brought about by Dr. Rush, is pleasingly related. The history of the New York Hospital is also briefly reported. Chapter VIII deals with the history of medical societies in the United States before the year 1800, and Packard tells us that the oldest medical society now extant is that of the State of New Jersey. The author deserves great credit for the care he has taken in the preparation of this chapter and of the next, which refers to the pre-revolutionary medical bibliography. Chapter X briefly refers to the laws passed by the various colonial legislatures regarding the practice of medicine. Chapter XI is devoted to a discussion of the discovery of anesthesia, and the author unreservedly gives to Dr. Crawford W. Long, of Georgia, the honor of having first used ether anesthesia for the performance of surgical operations, and fortifies this position with most conclusive arguments. To Dr. W. J. G. Morton is, however, accorded the credit of demonstrating to the medical profession and to the world the use of ether.

After reading this interesting book one can but feel that the medical profession owes Packard a debt of gratitude for the great amount of labor which he has spent in the preparation of this work, and for the entertaining manner in which he has related the many facts regarding the early history of medicine in America. It is just this sort of work which has been too much neglected by the medical profession in this material age, and it is a pleasure to see that one of its members has been willing to devote so much of his time to this labor of love. [J. H. G.]

The Walcher Position During Parturition.—Dr. Valère Cocq, (in *La Presse Médicale Belge*, 1901, No. 19), has reviewed the different positions suggested during labor. The erect position, in use yet among savage tribes, he advocates in primiparae during the first stage of labor. The dorsal position, the patient lying upon her back, is only indicated when great weakness exists. In normal cases he considers a reclining position, half down and half sitting up, advantageous until the head reaches the perineum. The genu-pectoral position is only indicated when certain pathological conditions exist, prolapse of the cord, or difficult version. The lateral position is the best when the head reaches the perineum. The Walcher position, extreme hyperextension, is brought about by placing a cushion under the sacrum to elevate it, the legs being allowed to hang freely. In this position the true conjugate is increased some millimeters. This may be advantageous when the superior strait is narrow, or in cases of contracted or kyphotic pelves. But it is not advised after the head passes the superior strait. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

The Kensington Hospital for Women.—During the month of May seventy-one patients were under treatment. There were thirty-five patients in the Hospital May 1st, and twenty-nine are under treatment at the present time. Fourteen abdominal sections and fifty-nine other operations have been performed. In the Dispensary there have been thirty-three new patients, who have made one hundred and twenty-seven visits.

College of Physicians of Philadelphia.—At the meeting of June 5, Dr. Jay F. Schamberg exhibited two patients showing epithelial cancer of the cheek treated by chemical caustics. The first patient was a woman of 83, who has only a short linear scar marking the site of an epithelioma of 15 years standing. The treatment consisted in the application of 25% carbolic acid ointment for a week and then a 50% solution of caustic potash followed by 25% arsenious acid. These applications were made after swabbing the parts with cocaine. In 4 weeks the growth was completely healed. The second patient was a man who is at present undergoing the same treatment.

Drs. J. S. Jopson and R. S. White reported a case of sarcoma of the large intestine in a boy of 4 years. Practically all the abdominal viscera were infiltrated by the growth. The literature of the subject was reviewed, 22 cases being recorded.

Dr. J. M. Spellisy read for Dr. Wilson and himself the report of over 100 cases of thermic fever and heat exhaustion in the Pennsylvania Hospital, occurring mainly in the year 1892. Dr. Spellisy reviewed at length the statistics of the hospital regarding the above cases. In 1764 the first case was recognized and was recorded under the heading, "Drinking Cold Water."

In the discussion Dr. Morris B. Lewis said that a great deal was yet to be done in the study of these cases by examination of the blood. Dr. J. C. Wilson stated that many of the symptoms were due to auto-intoxication and for this reason injections of salt solution should be employed in addition to treatment by cold. Dr. F. A. Packard spoke of some features of these cases which are not noted in the majority of the text books. First was the curious, mousy odor, which he considers diagnostic of thermic fever. Second is a crooning sort of groan emitted, which is also of diagnostic importance. Third, the character of the stools, and fourth the admixture of tonic and clonic convulsions. The lack of serosity of the blood is probably the cause of the symptoms and for that reason hypodermoclysis is indicated. Dr. James Tyson said that from the above view a possible explanation of the good effect of baths in the treatment was that submersion caused a certain amount of absorption of fluid. Recovery is generally more rapid when the patient is immersed than when he is simply rubbed with ice.

Suicide of Dr. W. H. Daly.—One of the remorseless onslaughts of fate was exemplified by the pathetic instances surrounding the death of Dr. W. H. Daly, at Pittsburg, Pa., Chief Volunteer Surgeon in the war with Spain in 1898. Major Daly was 59 years old and was one of the best known physicians in Pennsylvania. He was a close friend of Lieut. Gen. Nelson A. Miles, and after his appointment as chief surgeon of volunteers was assigned to duty on General Miles' staff at Tampa while the head of the army was at that place. His friends first noticed his despondency when the beef court of inquiry submitted its voluminous report, in which it criticised Dr. Daly's testimony regarding analysis of beef he had made. When his wife died at Garner, Iowa, several months later he became worse. His friends advised him to go away on a Rocky Mountain hunting trip and he did so. He frequently hunted with General Miles and William Cody ("Buffalo Bill"). After his return he did not show much improvement. He was a specialist in throat disease, but lost interest in his profession. About 9.45 o'clock on the morning of June 9 the body of Dr. Daly was found dead in the bath room

of the house in which he lived, and a 38 calibre revolver was found beside him with one chamber empty, the bullet having entered his right temple.

Poisoning of Dogs a Penal Offence.—A bill was introduced in the House making it a misdemeanor, punishable by a fine not exceeding \$500 and three years' imprisonment, to wilfully poison dogs.

Vital Statistics of Philadelphia for the week ending June 8, 1901.

Total mortality	410	Cases.	Deaths.
Inflammation of the appendix 3, bladder 1, brain 16, bronchi 2, heart 3, kidneys 20, larynx 1, liver 2, lungs 41, peritoneum 6, stomach and bowels 17, uterus 1			113
Marasmus 9, debility 7, inanition 12			28
Tuberculosis of the lungs			61
Apoplexy 10, paralysis 8			18
Heart-disease of 34, fatty degeneration of 3			37
Uremia 10, Bright's disease 5			15
Carcinoma of the bowels 1, breast 4, stomach 2, uterus 1, liver 1, neck 1			10
Convulsions			7
Diphtheria	63		
Brain-congestion of 1, softening of 2			3
Typhoid fever	120		12
Old age			7
Scarlet fever	77		5
Influenza 1, abscess, of breast 1, pelvic 1, liver 1, throat 1, alcoholism 2, asthma 2, atheroma 1, casualties 7, cerebro-spinal meningitis 1, congestion of the lungs 2, cirrhosis of the liver 3, consumption of the bowels 2, croup, membranous 2, cyanosis 3, diarrhoea 9, drowned 6, dropsy 1, dropsy abdominal 1, epilepsy 2, erysipelas 3, goitre 1, gangrene, lungs 2, hemorrhage from uterus 2, intussusception 1, jaundice 1, leukemia 2, measles 2, obstruction of the bowels 3, edema of the lungs 2, pyemia 1, rheumatism 2, sclerosis, spine 1, liver 1, septicemia 4, smallpox 1, sarcoma, lungs 1, pharynx 1, suffocation 1, suicide 2, teething 3, unknown coroner case 1, whooping cough 7			94

NEW JERSEY.

Monmouth Physicians.—The Monmouth County Medical Society held its annual meeting at the Monmouth House, Freehold, on Monday, May 20, 1901. Dr. C. Knecht, of Matawan, was the presiding officer. After dinner the society were addressed by Dr. Knecht, the retiring president, upon "An advance in clinical diagnosis." Dr. Forman read a paper upon appendicitis, in which he presented the consensus of the most recent views of the leading American surgeons upon this disease, and gave his personal experience as well as the results of treatment at the Monmouth Memorial Hospital. The following members were elected delegates to the N. J. State Medical Society: Drs. Long, MacMillan, Roberts, Shaw, Wooley and A. G. Brown. Officers for the ensuing year: Dr. Ed. F. Taylor, President; W. M. Hepburn, Vice President; I. S. Long, Treasurer; D. M. Forman, Secretary; Wooley, Reporter.

NEW YORK.

Cornell Medical College.—The third annual commencement of Cornell University Medical College was held June 5 at the college building in New York City. The degree of M. D. was conferred upon 26 graduates by President Jacob C. Schurman.

Dr. W. E. Young, recently in charge of the Randall's Island hospitals, has been appointed superintendent of the insane pavilion at Bellevue Hospital.

Dr. Frederick Peterson has been appointed Clinical Lecturer in Psychiatry in the College of Physicians and Surgeons, Columbia University.

NEW ENGLAND.

Smallpox in New England.—It is stated that smallpox is more prevalent in New England than it has been for many years. At Berlin, N. H., and Cranston, R. I., the number of cases is large. Smallpox is in Boston, 13 cases being in the Roxbury district. Galloupe's Island in Boston Harbor has 19 cases in quarantine, which came on a pest schooner from Cape Verde Islands. There are cases also at Providence and other places in Rhode Island; Marlboro, Worcester, Leominster, Fitchburg and other places in that State, and isolated cases in New Hampshire and Vermont.

Narcotics in New England.—Dr. A. P. Grinnell, of Burlington, Vt., has reported upon the use of narcotics in that State. He finds that every month there is sold, exclusive of patent medicines and physicians' prescriptions, 3,300,000 doses of opium. Some storekeepers refused to state the amount of sales of opium or its derivatives. These are not counted in the estimate, so that the actual amount is higher than that stated. About 40,000,000 grains of opium are sold a year.

WESTERN STATES.

Fiftieth Anniversary of the Invention of the Ophthalmoscope.—The section on ophthalmology of the American Medical Association devoted the greater part of its morning session on June 5th, 1901, toward observing the fiftieth anniversary of the invention of the ophthalmoscope. Dr. H. Friedenwald of Baltimore, Md., delivered an address on the origin and development of the instrument together with a description of the historic exhibit of the ophthalmoscope and publications on ophthalmoscopy prepared for this meeting. An address on the life of Helmholtz was delivered by Dr. C. A. Wood of Chicago, Ill. In a room adjoining the one in which the section met there was an exhibition of specimens and new instruments as well as some noteworthy publications, and especially ophthalmoscopy which was held under the auspices of the ophthalmic section which was held under the auspices of the ophthalmic section will be remembered with much gratification by those who witnessed it. The original pattern of Helmholtz stood out as a forceful reminder of its illustrious inventor and was surrounded by the models of its successors among which there were the patterns of Liebreich, Yaeger, Galezowski, Schweigger and others. There was an exhibition of the tools used in making the first American model of the Loring ophthalmoscope by machinery. The original article by Helmholtz entitled "Beschreibung eines Augen-Spiegels zur Untersuchung der Netzhaut im lebenden Auge" was also exhibited.

SOUTHERN STATES.

Dr. William Royal Stokes, City Bacteriologist in Baltimore, has been elected a member of the faculty of the College of Physicians and Surgeons in that city, and has been given the chair of pathology.

Dr. A. H. Kunst has been elected superintendent of the Weston (W. Va.) Lunatic Asylum to succeed Dr. W. E. Stathers.

Monstrosity Resembling a Mermaid.—The *Baltimore Sun* states that there was exhibited at the Health Department at Baltimore recently the body of a white child, normal from the waist up, but having instead of legs, a single appendage terminating in a four-toed foot. The child was dead when born. The monstrosity is a source of much interest to physicians, who declare it the most remarkable ever seen at the department, resembling, as it does in general appearance, the mermaid of fable. It will be preserved.

CANADA.

FROM THE SPECIAL CORRESPONDENT.

The Canadian Nurses' Association which has been seeking incorporation at the hands of the Dominion Parliament has not been very successful. When the measure was first brought before the House Private Bills Committee strong opposition developed against it, but after numerous amendments had been offered and the board of examiners so arranged that a majority of medical men would constitute its personnel the Bill was permitted to go before the House of Commons. Here, many and great objections were urged against the measure becoming law as it was thought to infringe on the rights of certain English and Welsh nurses now carrying on their profession in the Canadian Northwest Territories, as well as favoring the larger hospitals at the expense of the smaller. Finally the Bill received the six months' hoist; and during the recess of parliament the physicians throughout the Dominion are to be made more thoroughly acquainted with the scope of the measure. It shall probably be re-introduced the next session.

The Montreal Foundling Hospital is in need of a new, larger and more modern building. At the recent annual meeting held a couple of weeks ago, it was stated that the requirements of the hospital and the need of extra accommodation were so urgent that a new building would be absolutely necessary at no distant date. The medical report as well as that of the treasurer was submitted to the meeting. The latter showed that the receipts had been \$6,951 during the past year and that the disbursements had amounted to \$6,762, leaving a balance on hand of \$189. By the medical report it was shown that there were in the hospital on the 15th of May, one year ago, thirty-six babies, and there had been admitted since one hundred and thirty-seven, making a total of one hundred and seventy-three, or an increase over the previous years of twenty-two. Very nearly one half of the babies admitted were under one week old, and of these thirty-one were under twenty-four hours old. There were removed during the year by adoption, eight; by parents, twenty-six; death, one hundred and six; Protestant Orphan Asylum, one; and there remained in the hospital on the 15th of May, 1901, thirty-two. Pneumonia and bronchitis in a serious form, subsequent to la grippe, carried off many of the patients. An out-door dispensary will shortly be opened in connection with this institution.

The Ottawa Contagious Disease Hospital seems to be as far off in being established as it was over a year ago. Recently Mr. Justice Boyd, Chancellor of Ontario, has given judgment in Toronto, restraining the city of Ottawa from building a new hospital for cases of this character on the property of the Parks Commissioners, a judgment which will have a very serious effect upon the city. At the present time there are numerous cases of infectious diseases in the city and no hospital to isolate them. The provincial board of health has condemned the old site at Porter's Island in the Ottawa River. From the judgment of Chancellor Boyd, it would appear that the city and its board of health is absolutely powerless in the matter and can only expropriate land for temporary purposes in cases of emergency, but can do nothing towards establishing a permanent hospital. The city by-laws regarding the proximity of other buildings are very strict; and the suburban places object to the presence of a contagious diseases hospital in their midst.

The Doctors of Three Rivers, Que., met on the 30th of May in that city in response to a call to meet and organize a medical association for the advancement of the profession, the study of Dominion or Interprovincial Registration and other such like measures. The meetings will be held monthly, the next assembly to be held on the 24th of June. After organizing routine, the following officers were elected: Hon. President, Dr. Desaulniers of Nicolet; Hon.

Vice-President, Dr. Grenier, St. Maurice; President, Dr. L. P. Normand; 1st vice-president, Dr. Marchand; 2nd vice-president, Dr. H. Tudel; treasurer, Dr. J. H. Leduc; secretary, Dr. C. E. Darche; Executive Committee, Drs. Fiset, Lacoursiere, Planta, H. Desilets and Panneton. A committee to continue and complete the organization was named, the members of which are, Drs. J. E. Desilets, W. Ferron, Planta, Grenier, and Lambert.

Medical Research at McGill University is said to form part of the plan which the newly incorporated Rockefeller Institute of Medical Research is to carry on in several of the universities of the United States and Canada. It is understood that of the \$500,000 at the disposal of the Institute that McGill will have the use of \$50,000 to commence work with. The work will be conducted in the pathological laboratories of McGill under the supervision of Professor Adami.

Western Hospital, Montreal.—The annual meeting of the Committee of Management of this hospital was held on the 28th of May when the various reports submitted showed that the institution had just passed through the most successful year in its history. The medical report showed that at the out-door department there had been received for treatment 3,500 patients, as compared with 2,457 for the previous year. In the in-door department 396 were treated, against 380 for last year; there were 133 private patients as against 162 in the preceding twelve months, but the receipts from these had been more than for the previous year. Sixty-three per cent. of the patients in the wards were surgical cases. There had been twenty-four deaths or six per cent., and if the eight who died within forty-eight hours of their admission were deducted, the proportion would be only four per cent. The average daily cost of all the patients was 90 cents; of the public patients, 45 cents. The receipts totalled \$9,381.91 and the expenditure amounted to \$8,944.79. The debt was decreased from \$10,000 to \$8,000 and this in the face of many improvements.

Sir William Hingston is again the recipient of distinguished honor but this time by His Holiness, the Pope. The honor is the Papal Cross "for the Church and Pontiff" in recognition of his eminent services in the cause of charity and his unalterable devotion to the Church. His Grace Archbishop Bruchesi conveyed to Sir William, the gift of the head of the Church, which was accompanied by the following letter from Cardinal Rampolla, the papal Secretary of State:—"His Holiness has deigned to accord 'the Cross for the Church and Pontiff', to Sir William Hingston, as a recognition of his devotion and fidelity to the Church and its Supreme Head. The Cardinal Secretary of State has the pleasure to transmit him the diploma and the said cross, in order that he may wear it on his breast, as it is customary to do with other decorations."

Convocation at Toronto University was held on the afternoon of the 7th of June and the annual banquet of the Alumni Association in the evening thereof. Dr. R. A. Reeve, Dean of the Medical Faculty, and president of the Alumni Association, presided, and the Chancellor of the University, Sir William R. Meredith took advantage of the occasion to review the work and developments of the year. Speaking of the progress in the Medical Department: Three years ago the number who entered that department was sixty-one. Now it has reached the number of one hundred and twenty-four. The number of students enrolled three years ago was 230, while the number at the present time is 340, besides fifty-five occasional students. The department of pathology has during the past year had put at its head, Dr. J. J. MacKenzie in whom the Chancellor expressed the utmost confidence. Two recent graduates have received appointments as assistants in the department of anatomy of Cornell University. Sir William then proceeded to score the Ontario Government for unsatisfactory financial assistance to the university.

Dr. James Third, professor of medicine at Queen's Uni-

versity, Canada, had an attack of apoplexy recently and is not expected to recover.

Prof. J. George Adami, of McGill University, Montreal, Canada, has been appointed vice-president of the section of pathology and bacteriology of the International Congress on Tuberculosis, to be held in London, England, in July, under the patronage of his Majesty, King Edward VII.

MISCELLANY.

Obituary.—Dr. P. A. Harris, at Glendale, Ore., on May 30.—Dr. Allen T. Barnes, at Bloomington, Ill., on May 30.—Dr. James M. Stone, at Baltimore, Md., on June 5, aged 80 years.—Dr. Seth B. Sprague, at Jersey City, N. J., on June 5, aged 61 years.—Dr. D. C. Frost, at Mount Vernon, Ill., on June 5, aged 69 years.—Dr. William C. Parsons, at Chicago, Ill., on June 2.—Dr. E. Gansel, at Milwaukee, Wis., on June 2, aged 27 years.—Dr. Joseph E. Wright, at Philadelphia, Pa., on June 9, aged 43 years.—Dr. Edwin R. Lewis, at Kansas City, Mo., on June 8, aged 48 years.—Dr. A. J. Bloch, at Denver, Col., on June 8, aged 34 years.—Dr. E. P. Sale, at Memphis, Tenn., on June 8.

Dr. Van Buren Dixon, at Montevue Hospital, Frederick County, Md., on June 10, aged 62 years.—Dr. D. B. McKee, at Hutchinson, Kan., on June 10, aged 62 years.

A Dangerous Office.—According to the *London Daily Express*, an aurist, who was lately treating the Sultan, for an affection of the ear, accidentally touched the drum membrane, causing his patient intense pain. His Majesty, believing that an attempt was being made on his life, drew a revolver and shot the physician dead. A chamberlain, hearing the shot, entered, and the Sultan fired at him, and wounded him.

Plague in Turkey.—The Public Health Reports of June 7, 1901, state that in Bassora, Turkey, according to a supplementary communication of April 26, three persons have been taken sick with symptoms suspicious of plague, and have been strictly isolated in the hospital. In the house of the first 2 persons dead rats were discovered. The patients had not left Bassora for a long time and had never been in contact with any suspected plague patients. The rooms which these patients had occupied were at once disinfected and closed up.

The American Climatological Association.—At the annual meeting of the American Climatological Association held at Coronado, Cal., the following officers were elected: President, Dr. Samuel A. Fiske of Denver, Col.; Vice-Presidents, Dr. Norman Bridge, Los Angeles and Dr. W. F. R. Phillips of Washington; Secretary, Dr. Guy Hinsdale of Philadelphia.

Chinese Twins.—The *Medical Press and Circular* states that a double monster, technically known as "Xiphopagus," is now being exhibited on the Continent. The union between the twins is by a sternal band which is of a fleshy character situated in each of the two individuals at the lower border of the sternum. By means of the X-rays it has been determined that the communicating tissue contains no bones, but within it can be observed the peritoneum of each individual. The twins are described as very intelligent, mirthful, and fond of each other. The easiest position for the two to walk, run, and even leap is when they proceed forward side by side in a manner somewhat similar to two men forming a two-handed seat for the transport of wounded. Their functions are quite independent; in each the urine varies not only in regard to time but also in regard to quantity. While one sleeps the other may be awake, and there is great difference in the appetite of the two. The effect of alcohol has been noticed on the twins, for when on one occasion whisky was given to only one they both became intoxicated, and the one that had not tasted the whisky became much more so than the other. This is the eleventh known living instance of this peculiar kind of double monster, and it is a curious fact that the other examples have been born in mountainous districts; the present Chinese example, how-

ever, was born in a level country only slightly elevated above the sea. There was only one cord, and but one placenta.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended June 8, 1901:

			Cases	Deaths
SMALLPOX—UNITED STATES.

Changes in the Medical Corps of the Navy for Week ended June 8, 1901.

DOCTORS J. W. BACKUS, F. A. ASSERSON, J. F. MURPHY, W. SEAMAN and R. R. RICHARDSON appointed assistant surgeons in the Navy—June 1.
SURGEON F. J. B. CORDEIRO, detached from the Buffalo, June 10, and ordered home to wait orders—June 4.
SURGEON L. W. CURTIS, ordered to the Buffalo, June 10—June 4.
P. A. SURGEON E. S. BOGERT, JR., commissioned surgeon, from December 15, 1900—June 4.

ASSISTANT SURGEON R. W. PLUMMER, detached from the Nashville and ordered to the Princeton—June 6.
ASSISTANT SURGEON W. SEAMAN, ordered to the Independence, June 17—June 6.
ASSISTANT SURGEON H. H. HASS, detached from Naval Hospital, New York, and ordered to the Norfolk Navy Yard, June 10—June 6.
ASSISTANT SURGEON R. R. RICHARDSON, ordered to Naval Hospital, New York, June 10—June 6.
ASSISTANT SURGEON J. M. BRISTER, detached from the Independence, June 17, and ordered to the Asiatic Station via Transport Hancock—June 6.

Official list of the changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Service for the 7 days ended May 30, 1901.

H. R. CARTER, surgeon, to inspect the local quarantine station at Baltimore, Maryland—May 25, 1901.
R. M. WOODWARD, surgeon, granted two weeks' extension of leave of absence from May 25, 1901.
G. T. VAUGHAN, surgeon, detailed as delegate to represent the service at the meetings of the Association of Military Surgeons of the United States, May 30, and American Medical Association, June 4, at St. Paul, Minn—May 27, 1901.
J. C. COBB, passed assistant surgeon, relieved from duty at Fort Stanton, N. M., and directed to proceed to Portland, Oregon, May 29, 1901.
C. P. WERTENBAKER, passed assistant surgeon, detailed to represent the service at meetings of the Association of military surgeons of the United States, May 30; and American Medical Association, June 4, at St. Paul, Minn—May 27, 1901.
C. P. GARDNER, passed assistant surgeon, detailed to represent service at meeting of the Washington State Medical Society at Seattle, Washington, June 18 to 20, 1901, inclusive—May 27, 1901.
C. E. DECKER, assistant surgeon, granted leave of absence for 10 days—May 28, 1901.
W. C. HODBY, assistant surgeon, to proceed to Thomson, Ga., for special temporary duty—May 27, 1901.
J. W. HARGIS, acting assistant surgeon, granted leave of absence for 4 days from May 28, 1901.
E. T. OLSEN, hospital steward, granted leave of absence for 1 day from June 13, 1901.
L. C. SPANGLER, hospital steward, to proceed to Delaware Breakwater, Del., and report to medical officer in command for duty and assignment to quarters—May 28, 1901.

APPOINTMENT.

LEWIS C. SPANGLER, of Ohio, appointed hospital steward in the U. S. Marine Hospital Service—May 27, 1901.

GREAT BRITAIN.

Dr. Thomas Bond Commits Suicide.—Dr. Thomas Bond, a well known surgeon and analyst, committed suicide June 6, by throwing himself from a third story window of his residence. He had been suffering from melancholia for some time. Dr. Bond, who was the late Mr. Gladstone's surgeon, was noted in connection with investigations and discoveries in the cases of several sensational crimes, notably the Lefroy, Lamson and Camp murders.

CONTINENTAL EUROPE.

The New Siberia a Foul Dungeon.—The island of Sachalin designed by the Russian Government to take place of Siberia has been repeatedly condemned as an unsanitary place even for exiles, but all such demonstrations received denial from a few Russian hirelings. Now an official admits that the condition of the prisoners is far from satisfactory.

A New Journal to take the Place of the Vrach.—The present publishers of the *Vrach*, which by the will of its late editor is to be discontinued, ask permission to publish a medical journal entitled "*Russki Vrach*" (Russian Physician). Prof. W. W. Podwisotski and Dr. S. W. Wladislawlew will be the editors.

Sanitary Conditions of the Russian Isba.—Dr. A. Baloff, in describing the peasant's home in some parts of Russia, gives a graphic account of their mode of life. It appears that the entire family, often composed of ten or more persons, lives in one room badly heated, poorly ventilated and meagerly lighted. In this room they eat, sleep, cook, work and entertain themselves. Here the smaller domestic animals find a resting place, while the larger cattle dwell in a basement under the floor, which as a rule is made loosely enough to admit the odors from below. In some houses there are no chimneys and during the process of heating the oven the smoke finds its only exit through the open door.

Society Reports.

FIFTY-SECOND MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

GENERAL SESSION.

FIRST DAY, JUNE 4th, 1901.

The General Session convened in the Metropolitan Opera House, St. Paul, Minn., at 10.30 A. M. The meeting was opened with prayer by Bishop Whipple, the audience joining with him in the Lord's prayer. The Association was welcomed by the Mayor of St. Paul. The State of Minnesota, he said, showed a remarkably low mortality record, due, he believed largely to the work of the medical profession. He suggested that any patients whom the visiting members could not cure be sent to St. Paul and that they would be sent back in such condition, if not living monuments of professional skill, at least they will live long enough to be useful members of society. The Governor of the State who had been expected, was, through a misunderstanding of two invitations, not at the meeting. Dr. Reed requested that the former Presidents and Vice Presidents come to the platform. In approaching the discharge of his duties as President of the 52nd meeting of the Association, Dr. Reed expressed his appreciation of being called to such a conspicuous honor, an appreciation all the more pronounced when he reflected upon the magnitude and achievement of this great national body, and upon the lustre of the distinguished men who had presided over these deliberations. A sad duty was to bring to the attention of the members the fact that since the last reunion three of the most illustrious predecessors had been called to their reward. They were Alfred Stille, Louis A. Sayre, and Hunter Maguire, each a former president, and they had died within a single week. It was urged that steps be taken to secure portraits of the gentlemen to be placed in a gallery until the Association shall have a proper repository for them. It was also recommended that suitable formal action relative to the life and distinguished services of these lamented confrères be taken by the Association. In his address the President called attention to the satisfactory condition of the affairs of the Association as indicated by the consolidated report of the Treasurer and Board of Trustees, showing under the judicious management a balance at the end of the fiscal year of \$31,400.67, being an excess of over \$3,000.00 over the preceding year. There was safely invested the sum of \$25,000.00, to be appropriated to the purchase of a home for the Journal. The circulation shows a large excess over any other weekly medical journal in the world. An expression of appreciation of the valued service of the accomplished Editor, Dr. George H. Simmons, was tendered. The incorporation of the Association was highly commended, without which much of the success could not have been attained. Although the circulation of the Journal was so satisfactory, it was a matter of some regret that it exceeded the membership of the Association by $2\frac{1}{2}$ times. The question was considered whether the accumulated funds should be applied to the further exploiting of the Journal, establishing a home for the Association, should the members receive annual dividends, or should the money be devoted to original scientific research on subjects of universal interest to the profession. The President ventured the suggestion that a reserve should be held in hand large enough to meet possible contingencies in connection with the Journal. He advocated that the present generous policy regarding the conduct of the Journal be continued. The question of tuberculosis, the tenement house problem, the prevention of endemic diseases, and many subjects of a specific character demanded the fostering care of the Association. The subjects he hoped would be taken up subsequently under auspicious circumstances. The inefficiency of the profession in its influence upon Congress was deplored and special mention made of this lack in connection with the Army Medical Corps. That which discriminates against the status of the Army Medical Corps strikes at the status of every medical man in the country, and it becomes the duty of every medical man to resent as a personal stigma legislation adverse to the Army Medical

Corps. It behooved the Association to put itself in position to influence the largest number of votes; every physician should in a respectable sense become an active politician. The status of the medical profession in relation to the Commonwealth was stated to be that of the largest, truest and most intelligent of the world, moving in harmony with the most advanced influences of civilization. The necessity for complete organization of the profession was touched upon. Certain results could only be attained by the unification of the profession. In the progress of the profession events of to-day proclaim the existence of a new school of medicine as distinct from the schools of 50 years ago as is the Christian dispensation from its Pagan antecedents. It is a school of human tolerance and scientific research, ready to abandon a truth of yesterday if it be demonstrated an error of to-day. It recognizes that he is the greatest among men who reveals the most truth. It examines all things; it judges all things. Upon the deliberations of the exponents of "this new school of this new generation of this new century," the representatives of the democracy of science, the President invoked the spirit of courage, the spirit of progress, the spirit of truth. On motion the address of the President was referred to the Executive Committee with instructions to report to the Association upon its many valuable recommendations. A portrait of Dr. N. S. Davis was presented to the Association, recognized as pre-eminently the founder of the American Medical Association, and for more than 50 years its most constant, eminent and faithful guide in every department of its work, one who has been a pioneer investigator in the department of physiology and in the field of preventive medicine, an untiring and valuable contributor to medical science and literature and who has enjoyed the highest honors that his profession could bestow as President of this Association, and of the Ninth International Medical Congress; one who in his own city organized the first general hospital and established clinical instruction therein, and who was one of the founders and active supporters of the Chicago Relief Hospital for the Poor, the Chicago Academy of Sciences, the Historical Society and the Chicago Medical Society. Though Dr. Davis is in his 85th year of life and 65th year of medical practice, he still devotes 5 or 6 hours daily to his patients. He is happiest when contributing most to the happiness of others. A motion was adopted for the appointment of a Committee for securing to the Association, without cost, the portraits of the ex-Presidents of the Association. The hope was at the same time expressed that the time might come when the Association would have a magnificent home, a building of its own wherein might hang the portraits of the living ex-Presidents, President of the Association and those of the noble men who have gone beyond. The report of the Secretary showed the present membership to be something over 10,600, an increase of 1500 or 1600, the largest increase in any year in the history of the Association. There had been submitted to the Judicial Council for action the correspondence in regard to two cases of membership. The report of the Executive Committee called attention to a gratifying diminution in the number of papers offered in the different sections in accordance with a former recommendation. The total number on the program was 391 as against 491 last year and 615 in 1898, the largest number being in Practice of Medicine—43 papers. Attention was called to the rule that abstracts should be furnished and compliance urged. The report further stated that the pathological lecture by Dr. Simon Flexner, of Philadelphia, could not be given, Dr. Flexner being unable to be present. The Report of the Board of Trustees combined with it the report of the Treasurer a detailed account of which had been circulated. The financial policy of the Journal had been a success. It was urged that there should be no change in the program after May 30th of each year; previous changes had much increased the expenses of this department. It was suggested that too many papers were read by title and that if a man on the program for a paper did not consider it of sufficient worth to be present and read it, it should be treated as a volunteer paper and should so appear in the paper of the Journal. Preference should be given to the men who write but one paper. In order to further improve the quality of the work the Trustees would submit that no paper presented to any section should be printed until it received the approval of three members of the Executive Committee of that section, evidenced by their signature. Dr. Gordon, of Maine, thought the Journal had been

used long enough as an advertising medium for men who sent papers to be published and did not attend the meetings, and he was glad the Committee had taken the matter in hand. He also hoped that the violation in taking 40 minutes to an hour for reading a paper and 20 to 40 minutes for discussion would be corrected. Dr. J. R. Pennington, of Illinois; Dr. Louis Rodman, of Pennsylvania, and Dr. Dandridge were appointed a Committee to secure portraits of the ex-Presidents of the Association and invested with the power to deposit them in some art gallery until a proper place can be provided by the Association. The Committee on National Legislation reported that the Anti-vivisection Bill had probably been defeated; that the bill giving additional power to the Marine Hospital Service had been passed, and that the defeat of the bill increasing postal-rates had been accomplished. The Committee further reported that the medical societies of the several States and territories are appreciating the importance of State co-operation in medical matters. The Committee was present at the conference held in Washington in February and appointed a standing committee of the Annual Conference with power to act for the various States and territories. It was recommended that the American Medical Association request affiliated societies of States and territories to provide in their constitution for the appointment of their State Legislation Committees, whose duty shall be to consider all medical legislation arising in the State Legislature and Congress and to advise the constituent members thereon. The report of the Committee on Reorganization was on motion referred to a joint committee composed of the General Executive Committee and the enlarged Committee on Reorganization representing all the States, with an opportunity for a hearing of those who desired to discuss the subject, and that a report be made in the General Session the following morning.

ORATION ON SURGERY BY DR. JOHN A. WYETH.

The Value of Clinical Microscopy, Bacteriology and Chemistry in Surgical Practice.

The surgeon of experience soon learns that it requires more than asepsis and the rapid and skilful performance of an operation to achieve the fullest measure of success. It is essential in the highest degree to call into requisition the invaluable aid which laboratory research alone can give to make a diagnosis accurate, and to indicate the rational measures of treatment before, during and after the operation. Chemical analysis, clinical microscopy and bacteriology should form part of the educational requirements of the surgeon. Laboratory research has placed not only the medical profession but the entire human family under lasting obligations, and has done more than all else in accomplishing the revolution in surgical thought and practice that has taken place. The discovery of the bacillus of diphtheria alone would emphasize this statement, since it has had its logical sequence in Behring's invaluable discovery that the blood of animals rendered immune to diphtheria by inoculation contained a substance capable of neutralizing the effects of this bacillus and its toxin, reducing the death rate of diphtheria from its former mortality to the insignificant rate of the ordinary disease.

What is true of diphtheria is undoubtedly true of all pathogenic organisms, the spirillum of cholera, the pneumococcus, tetanus, and other similar organisms. The elaboration of the typhoid bacillus by Eberth and Gaffky with Widal's demonstration was an invaluable discovery, and will be the means of saving innumerable lives since it affords an early and accurate diagnosis as indication for, or against a surgical operation. The laboratory has made clear the diagnosis and treatment of actinomycosis, anthrax, malignant edema, bubonic plague and other diseases.

Bacteriological research has robbed the puerperal state of its great anxiety and dread; not only by preventing sepsis, but by recognizing the character of the infection already established in time to prevent general peritonitis or septicemia, and enables us to determine whether or not the infection is of a type sufficiently grave to justify a hysterectomy and drainage instead of curetting.

Chemical analysis of the stomach juices and of the contents clears up many doubtful conditions of this organ, and enables the surgeon as well as the physician to determine whether or not free hydrochloric acid exists, and the quantity of this fluid.

The test breakfast of Ewald and Boas, and the more elaborate test meal of Germain See enables us to determine the exact condition of the organ; as in the presence of lactic acid, which is dependent upon a special bacillus thriving in the stomach only under abnormal conditions, the diagnosis of carcinoma is practically established.

In the differentiation between the pathogenic organisms of specific and non-specific urethritis, microscopy and bacteriology are our only infallible guides. They teach us to eliminate the various bacteria not bearing directly upon the etiology of urethritis, and to recognize distinctly the two forms of diplococcus, the gonococcus of Neisser and the pseudo-diplococcus. Bearing in mind the fact that these dangerous organisms may remain dormant in these passages for months, or for years, incapable of a further inoculation of the seemingly immunized patient, but capable of exciting the most acute and injurious inflammation in an innocent victim, it becomes a matter of the greatest importance to subject to most careful study the external genito urinary passages where an infection has once existed.

In pyelitis the differentiation between simple pyogenic infection and the presence of the bacilli of tuberculosis can be determined by laboratory research without the extreme measure of exploration. In fact, pathological conditions of the substance of the kidney, the calices, the hilum, the pelvis, the urethra and the bladder, and important changes in the tissues beyond these organs are evidenced by the presence of oxyuria.

Uric acid and the various other deposits in the urine, results of abnormal conditions of the digestive and assimilative apparatus, are made evident by the microscope and by chemical analysis, and are of invaluable aid to the surgeon.

In glycosuria he must know whether he is dealing with what Pavy designates "alimentary diabetes," in which the sugar eliminated by the urine is derived solely from the food as result of defective carbohydrate assimilation, or whether that almost hopeless condition of "composite diabetes," in which abnormal disintegration is taking place, is present.

No less important is the estimate of the amount of urea which can be determined by the simple laboratory process of Doremus.

The presence of blood when not made clear by the eye or the microscope, is now evident in the fine chemical test in which the blood crystals of Teichmann may be recognized even while the corpuscles have entirely disappeared.

One of the most attractive subjects of laboratory research is the blood, and although hematology is practically in its infancy, many valuable discoveries have already been made, and in the proper study of a surgical case a knowledge of the blood is as essential as that of the urine. It gives us information in regard to anemia, and often tells us whether it is a type of blood impoverished which can be corrected, or whether it is of the graver or more pernicious form which would either preclude an operation, or, if this were absolutely necessary, would enable him to announce to those entitled to information, the gravity of the outlook.

The determination of the richness of the hemoglobin by von Fleischl's hemometer, or a count of the red cells and of the leukocytes, and the differentiation of the various types of cells all point clearly to certain conditions which it is the duty of the surgeon to comprehend.

In the early recognition of septic process, chiefly pyogenic, surgery can no longer disregard the value of the blood count, and this is especially valuable in the early stages of those inflammatory processes which occur in the peritoneal cavity.

We know that in a certain proportion of cases of infection, temperature does not always indicate the increasing gravity of the lesion, while the degree of sepsis can be in great measure determined by the leukocyte count. In impaction of feces, extrauterine pregnancy, floating kidney, gall-stone colic, renal colic, ovarian neuralgia, intussusception, volvulus, internal hernia, twisted pedicle, etc. there is no leukocytosis unless complicated with an acute septic process. In abscess of the liver, the leukocyte count ranges from 12,000 to 48,000, while there is a marked increase in all the septic pyogenic processes of the lungs and the pleura.

In osteomyelitis the leukocyte count ranges as a rule from 15,000 to 25,000, and at times higher. Since in the early stages of this disease it is at times difficult by sub-

jective symptoms to differentiate between rheumatism or gout, the leukocyte count is invaluable in demonstrating at once the pyogenic process.

In that very rare disease, trichiniasis, the leukocytes register sometimes as high as 30,000, but the special feature is the presence of a large number of eosinophile cells, sometimes as high as 50%, and in rare cases 67% of the total number of leukocytes being reported within this form of corpuscle. A very considerable number of cases have been reported within the last year in which the diagnosis had been determined by the presence of eosinophiles.

Not only can the presence of the plasmodium malariae be recognized between the different varieties of the malarial parasite. It has shown that the tertian organism takes forty-eight hours to develop and undergo sporulation, the quartan 72, while the estivo-autumnal passes through irregular phases, varying from forty-eight hours to several days.

We are enabled to demonstrate also the presence of the spirochaete of relapsing fever discovered by Overmeier in 1873. Although the cork-screw or spiral threads are rarely seen unless the blood is examined in the height of the fever paroxysms, diplococcus-shaped bodies believed to be the spores of this organism are found in the periods of remission.

SECOND DAY, JUNE 5th, 1901.

The meeting was called to order by the president at 11 A. M. President Reed then introduced Governor S. R. Van Sant, who as the chief executive of the State, stood for every interest promotive of the highest and most advanced stand in medicine; who exercised a fostering care over the State University, the fame of which extends throughout the land. Governor Van Sant remarked that his welcome was none the less cordial from being 24 hours late, and that age improves some things used in the medical profession. Referring to the possibility of the next meeting being held in the South he stated that when the Grand Army Reunion was held in Louisville a royal welcome was given. At night electric lights blazed forth with the words, and even over the jail in great large letters was the word "Welcome." The medical profession, he sometimes thought, had special privileges. For instance "if I treat you I pay the bill, if you treat me or my family I pay the bill still." The address closed with the expression of a most cordial welcome to the city and State. The minutes of the preceding meeting were read by the Secretary, Dr. George H. Simmons. The report of the Joint Committee consisting of the Executive Committee on Organization upon the report of the Committee on Reorganization was read by Dr. Walker, of Michigan. The Committee recommended on motion of Dr. Reynolds that the instrument of the whole and amended was adopted. The President stated that in view of the fact that some modifications of minor importance had been made, he thought, in the interest of fairness, it would be well for the assembly to listen to a reading of the entire document as about to be presented for final consideration. The document was read. Dr. L. D. Buckley, of New York, thought that all would recognize that the time was one of the most crucial in the history of the organization, one to test the willingness of the members to do that which seemed best for the good of the profession at large. From being first opposed to the reorganization he had been convinced after repeatedly fighting the changes proposed. The question had been fully considered by representative men who had been most patiently heard time and again by the Committee in going over the sections. Considerable changes had been made; one of particular value was that the house of delegates should have two representatives from each section instead of only one, making it possible for a large number of scientific men to attend the meetings. He called attention to the fact that in 1887 Dr. Davis had wanted the present change and in 1891 another similar effort had been thwarted. A number of things of smaller importance were not entirely satisfactory, but these could be adjusted by the house of delegates. He moved that the recommendation of the Committee be unanimously adopted. Dr. McCormack, of Kentucky, moved that if the question was to be discussed those holding opposite views should be heard alternately. He wanted the Association to understand that the earnest desire of the Committee was that those opposing or favoring the recommendation be fairly heard. The motion to accept the report of the Committee on Re-

organization was seconded and carried by a large majority. The oration on Surgery was afterward given by Dr. Weyth.

THIRD DAY, JUNE 6th, 1901.

In calling the meeting to order Dr. Reed announced that he had agreed with the Committee of Arrangements to allow ten minutes to the representative of the American Woman's Christian Temperance Union relative to entertain questions of sanitation in the army. The meeting was then addressed by Miss Susan B. Anthony and the Rev. Anna M. Shaw. Miss Anthony said in part: "It is with great fear and trepidation that I come before you this morning to speak upon a question very near the heart of all true women. You are, many of you, in favor, and some opposed to the system of regulating vice in Manila, Hawaii and Porto Rico and our new possessions. We call to your attention the fact that when you gather up the young men for the army you take them from the care and protection of the home. We ask you to remember that these are the sons of mothers who are watching and caring for their boys and care more that they should be returned unpolluted than that they shall not come at all. If need be, better their death than their ruin. It is the man who proves untrue to one woman who loses the respect for all. I call your attention to the fact that when our Northern army made its pilgrimage through the South with Sherman's march to the sea, it left a whole army of children to be born of the mixed races. When the army leaves Manila and the Philippines this tract is left. The race is being degenerated. We shall be lost, as we might say, in this condition. I hope you will in making or influencing any resolution, for you know your opinion will go far in influencing Congress, take the position that it is your own son, your own daughter who is involved." Rev. Anna M. Shaw then addressed the meeting urging that any resolutions passed by the American Medical Association might stand for the principle that virtue must always be protected everywhere and under all circumstances, for there is no part of God's universe in which virtue should have greater protection than under this government, which stands before the world as the greatest Christian civilization under the light of the sun. Dr. Seaman, of New York stated that vital statistics of the army in Pekin show that 50 per cent. of the patients treated were affected with venereal disease, and since the abolition of the army canteen the extent of these diseases had doubled. He thought the misguided enthusiasts who had opposed the army canteen should not further indulge in their self-congratulation, but stop interfering with matters in the army which they did not understand. Before Dr. Seaman had finished his statements, hisses were heard in some parts of the audience, and cries of "Time," "Time," were being shouted from all parts of the house, while cheers and applause came from other sections. President Reed declared that the session would proceed with its usual business. The Trustees were authorized to grant the Reorganization Committee \$400.00 to pay the expenses they had incurred in preparing the new constitution. The Committee on Legislation was continued. The recommendation of the Executive Committee that a committee of three be appointed to revise the Code of Ethics called forth a lively discussion. On the first reading of the report Dr. Happel, of Tennessee, had demanded that this recommendation be considered separately. "We have had enough railroading at this meeting of the Association," said the doctor. "If the Association desires a new code, I suppose I can live as I did in the sixties, under almost anything, but let us have the action fair and open." It was moved that the recommendation of the Executive Committee lay upon the table. The vote seemed about evenly divided and the Chair could not decide. Dr. Happel demanded a roll call. The Secretary announced that there were about 1300 delegates whose credentials had been received. Dr. Happel stated that if the gentlemen who were urging revision insisted upon bringing the matter to a vote at this session he would stand by the demand for a roll call, and that the session would not finish its business today or tomorrow. Dr. Bishop, of Pennsylvania, moved that the calling of the roll be postponed until the next annual meeting of the General Session. This brought forth a hearty round of laughter and the motion was carried by a large majority. The recommendation for the fusion of the sections on pathology and bacteriology, and of that on physiology and dietetics, was adopted. A motion was made for the appoint-

ment of a committee of three to influence the appeal of the law abolishing the army canteen. An objection was made that such a resolution would not be creditable to the American Medical Association, certainly not in consonance with the sentiments of the founder of the Association, Dr. N. S. Davis, whose portrait had just been presented to the Association. The object was over-ruled and the matter referred to the standing committee at Washington. A resolution was passed that the American Medical Association disapproves of the act of Congress in failing to pass a bill which provided for the proper and adequate recognition of the medical corps of the United States Army. A resolution was passed favoring the establishment in Washington of a psycho-physiological laboratory. The oration on Medicine was delivered by Dr. N. S. Davis, Jr., of Chicago. Dr. Davis reviewed the advancement in medicine during the past century and declared that progress had been more rapid than in any other. Death rates from many causes had decreased among civilized people. Some diseases, such as nervous ailments, had been more rapid than in any other. Death rates from any cause had decreased among civilized people. Bright's disease and heart disease had increased owing to more rapid ways of living. Better sanitary regulations and more temperate habits had checked the spread of diseases. The public must be educated in sanitary and health truths in order to better prevent disease. It is to be hoped that physicians will learn to measure more accurately the effect of drugs so as to reduce the number of drugs and the quantity used. Medical men must depend largely on the aid and faith, the faith of the patient that all will be done for him that can be. Antitoxin for diphtheria had reduced the death rate and led to hopes that an antitoxin would be discovered for typhoid, pneumonia and other fevers. The following officers were elected for the coming year: President, Dr. John A. Wyeth, of New York City; First Vice-President, Dr. Alonzo Garcelon, of Maine; Second Vice-President, Dr. A. J. Stone, of St. Paul; Third Vice-President, Dr. A. Y. Jones, of Nebraska; Fourth Vice-President, Dr. John R. Dibrell, of Arkansas; Treasurer, Dr. Henry P. Newman, of Illinois; Secretary, Dr. George H. Simmons, of Illinois; Librarian, Dr. George W. Webster, of Illinois. Board of Trustees: Dr. W. W. Grant, Denver, Col.; Dr. John F. Fulton, Minn.; Dr. T. J. Happel, Tennessee. Judicial Council: Dr. George Cook, N. H.; Dr. H. H. Grant, Kentucky; Dr. John B. Murphy, Illinois; Dr. Philip Marvel, of New York; Dr. Louis H. Taylor, Pa.; Dr. John C. Dawson, S. C., and Dr. N. Fred Essig, Washington. The following selections were made for preparations of the General Session for next year: On surgery, Dr. Henry Sherman, Cal.; on medicine, Dr. Frank Billings, Ill.; on State medicine, Dr. J. M. Emmert, Iowa. The place of the next meeting is Saratoga, N. Y.; Dr. G. Y. Comstock to be Chairman of Committee on Arrangements.

FOURTH DAY, JUNE 7th, 1901.

The final session was called to order by the President at 11 o'clock. A vote was taken in favor of re-establishing the army canteen. The oration on State medicine was delivered by Dr. George B. Kober, of Washington, D. C. Dr. Judson Daland, of Philadelphia, was appointed delegate to the World's Tuberculosis Congress in London during July. A resolution was adopted thanking Mr. John D. Rockefeller for his generous gift of \$200,000 donated to the cause of scientific research under the direction of Dr. William H. Welch, of Johns Hopkins University. President Reed named ex-Presidents Dr. H. O. Marcy, of Boston, and Dr. Magruder, of Washington, a committee to escort the President-elect to the platform. Dr. Wyeth said he was inclined to follow the precedent established the previous day, and to postpone until the next annual meeting of the Association any remarks he might have to make; that he appreciated most deeply and fully the honor conferred upon him. "It will take my best efforts," he said, "to repay the Association even in part for what it has done, but such as they are you will have them, and I will do, as in the past, my best for the highest, most generous, noblest interests of medicine and surgery of our country." A motion was adopted thanking the retiring President, the Committee on Arrangements, and the physicians of the Twin Cities, for the splendid management of the convention. Dr. H. O. Marcy, of Boston, called for a rising vote of thanks to the President who had presided over their meetings with such courtesy and rare fairness, and to the officers of sections.

and to the citizens of the two cities. President Reed spoke of the extreme harmony which had prevailed, and of his belief that the meeting would redound to the welfare of the profession. In returning thanks for the resolution, he said: "I feel a sense of personal obligation to you, gentlemen, to the officers of the sections, to the faithful and efficient Secretary, and to those distinguished gentlemen from all over the country, who have come to this convention, bringing the best garnered efforts of their experience whereby we have this week given to the world the best scientific program in the history of the American Medical Association. My administration, while a source of some labor, has been a source of constant pleasure, for I was confident every moment of the co-operation of those whose co-operation meant success." The 52nd annual meeting of the American Medical Association was then declared adjourned.

SECTION ON PRACTICE OF MEDICINE.

FIRST DAY, JUNE 4th.

J. M. Anders, M. D., of Philadelphia, in the Chair.

Dr. J. M. Anders, of Philadelphia, delivered his address and attempted to point out a few lines on which the organization and professional progress should be conducted. He believed that if the American Medical Association hoped to be one of the great powers of the country it was of great importance that the proposed reorganization scheme be promptly effected and due efforts be made to establish and maintain proper respect and forbearance between the various sections to the end that they may work in perfect harmony with one another.

Dr. John B. Deaver, of Philadelphia, then read a paper on **appendicitis**. He stated that the appendix was the most vulnerable of all the abdominal organs for the following reason: It is a structure in the process of retrograde metamorphosis; it is deficient in blood, nerve and lymphatic supply; it is long and its calibre is small, hence its drainage is easily interfered with; it is subjected to traumatism by the movement of the psoas muscle upon which it lies. Therefore it is apparent that the appendix may easily become the target for the destructive micro-organisms where from any cause these are incited into activity; and it is especially noteworthy that a hollow, glandular organ remains intact only so long as the production and evacuation of its secretions continue normally. When this function is deranged there are first, retention, stagnation, and decomposition of the appendix contents; second, pressure leading to ulceration of the appendix wall; third, and the most important, the bacteria, especially the colon bacilli are so increased in number and virulence that they are able to penetrate the coats of the appendix and set up their irritant processes in varying degrees. Such he considered to be the brief pathogenesis of appendicitis.

The following classification was suggested as convenient and well founded:

Acute Appendicitis:	First—Catarrhal.
	Second—Interstitial.
	Third—Ulcerative.
	Fourth—Gangrenous.
Chronic Appendicitis:	First—Catarrhal.
	Second—Interstitial.
	Third—Obliterating.

He had never seen much good from the efforts of nature to cure. The abscess itself, by its tendency to infect the peritoneum, is a grave menace, and even if the abscess ruptured into a hollow viscus the situation is not much better. The speaker then considered certain features of the pathology and two points were especially emphasized: First, the practical non-existence of any form of inflammation which by obliterating its lumen rendered the appendix harmless. Second, the appalling rapidity and suddenness with which the appendix may suffer bacterial invasion and necrotic degeneration with resulting general peritonitis. Upon these two facts he based proper treatment and the justice of claiming appendicitis as a purely surgical affection. No disease presented its signs and symptoms in such varied form and locality as appendicitis, and he made it a rule therefore, in all abdominal cases, to first exclude appendicial irritation, because careful examination will

often reveal as due to it the affections otherwise apt to be classified as "enterocolitis," "acute dyspepsia;" "cholera morbus," etc.

In all inflammations of the appendix there are three cardinal symptoms, viz.: pain, tenderness and rigidity. Pain is by all means the most significant, so much so that the speaker regarded with suspicion every clinical history with belly-ache, inflammation of the bowels, neuralgia of the stomach, etc. The pain of appendicitis is paroxysmal, cramp-like and colicky and may at intervals almost disappear. It is usually first referred to the umbilical and epigastric regions becoming localized in the right iliac fossa, only after the lapse of several hours, and that not in all cases. He advised that we should at first examine away from the disease, and then slowly and gently approach the tender area. A localized spot of extreme tenderness he considered to be surest indication of pus formation; conversely abrupt cessation is apt to denote complete gangrenous change and a paralysis of peripheral nerve filaments by toxin absorption. After referring briefly to some of the other symptoms of appendicitis he stated that he did not depend to any extent upon blood examinations; a leukocytosis of over 20,000 indicates pus usually unless either shut off by adhesion or the individual is overwhelmed by septic absorption. The symptoms of appendicitis are seldom in proportion to the appendix regions, therefore it should suffice to diagnose early the inflammatory involvement which is of itself proper enough indication for rational treatment. He did believe there was but one treatment for appendicitis, viz.: the aseptic scalpel of a surgeon, and it should be called upon as promptly as the diagnosis was made.

Dr. DeLancey, Rochester, of Buffalo, N. Y., made a strong plea for the blood count as a diagnostic aid of these conditions during the acute inflammatory state and particularly during the development of pus. With an elevation of temperature there was usually a higher leukocytosis. He also believed that the aseptic scalpel was the only treatment for appendicitis.

Dr. J. B. Kelley, of Philadelphia, did not think that any medical man should treat a case of appendicitis after the first twenty-four hours.

Dr. J. B. McElroy, of Mississippi, read a paper on **some phases of malaria**. In this he related in detail a case in order that he might discuss some of the phases of malaria that were suggested by it. In referring to the perniciousness in malaria he said that it was a well-known fact that in these affections the aestivo-autumnal parasites are found in very large numbers. There are usually two predominating broods of parasites in the blood of patients with pernicious fever, but Marchiafava and Bignami report cases in which the viscera as well as the peripheral circulation show a very small number of parasites. It is evident that we must look for the causes of malignancy in some other direction than merely in the large quantity of parasites. These causes may be found in what has been termed in the biological characteristics of the aestivo-autumnal parasites. The first of these is their capacity for rapid propagation. It is another characteristic of these parasites to disappear from a peripheral circulation to complete their cycle of development in other vascular areas. Another factor in the forms of pernicious malaria, the virulence of these parasites, should be taken into account. Many attempts have been made to demonstrate a malarial toxin, and there is good evidence to believe that such exists although it cannot be demonstrated. It is, therefore, probable that this property of the aestivo-autumnal parasites more than any other accounts for malignancy in malaria. Another proof of the great virulence of these parasites is the occurrence of hemoglobinuria in these affections than the mere offers other evidences of malarial infections than the mere pigmented leukocytes, and the characteristic leukocytic variation of malarial infection. In all the cases studied by him there were pigmented leukocytes. After quite an exhaustive consideration of this subject he stated that if pigmentation and leukocytic variation are evidences of malarial infections where the parasites are few or absent in the peripheral circulation, hemoglobinuria must be malarial, and being malaria, is a most striking evidence of the virulence of the aestivo-autumnal parasites. Phenomena occurring in these infections after the disappearance of the parasite, which have been termed post-malaria, are also evidences of the toxin theory.

It has not infrequently been stated that the negro is relatively immune from malarial infections. These statements are not in accord with his experience of eight years with the negroes living in the Southern Mississippi valley. On the plantation where he resided there were 24 whites, of whom 41 were infected with malaria. There were 184 blacks, and of these 61 were infected.

In considering the subject of gangrene he said that Professor Osler divided it into three groups: First, in connection with Raynaud's disease; second, multiple spontaneous gangrene in association with the acute infections like measles, typhoid fever, typhus fever, scarlet fever, diphtheria and malaria. Multiple spontaneous gangrene of the limbs in young and middle-aged people may occur without any obvious cause. The case he reported was one of multiple gangrene in aestivo-autumnal infections.

Dr. E. H. Martin, of Mississippi, said that hemoglobinuria was pernicious, not in the sense that pernicious is usually regarded; it was malignant in that the germs cause an absolute destruction of the blood cells. In the other forms he considered there was simply an overdose of the toxins. In the negro very few cases of pernicious malaria were seen in proportion to the number of cases of malaria met with. In small children, especially among the whites, they had a great many cases, and it was unusual for a family to raise two out of five children in Mississippi on account of pernicious malaria. The blood of the children was very rich in the necessary pabulum for the malarial germs, and the child, when small, having but poor resisting power, the germs attack the child and there is really an overdose of malaria.

SECOND DAY, JUNE 5th, 1901.

Dr. W. D. Kelly, of St Paul, read a paper on **The Clinical and Microscopical Examination of the Blood**. The blood serum containing serum albumin and serum globulin is subject to chemical changes in puerperal septicemia, and in certain febrile diseases the globulin is less subject to change than the serum albumin. Pathological variations in the phosphates are but slight, and of the chlorides not very great, although this principle is chiefly responsible for the isotonic relation of cells in serum. In anemia there is usually a high percentage of chlorides. The larger the proportion of plasma the greater is the percentage of chlorides in the blood. In the plasma are chiefly found the sodium salts; these are usually increased in watery blood. Potassium found in the red cells is diminished in hydremic conditions. Chauveau, Seegen, Cavazzani, and others found, in normal blood, traces of glucose, which was increased by a diet of carbohydrates and diminished by muscular exercise. In the red cells is found the diastase, also in the serum, and Precka and others believe it to have the power of coagulating the blood; it is inhibited by neuclein and increased by sodium sulphate and chloride. Fat has been demonstrated in the blood after a hearty meal. Free fat, both in health and disease, has been frequently found. Acetone has been found in fevers. V. Taksch demonstrated fatty acids in the blood in leukemia, acute yellow atrophy of the liver and infectious diseases.

In cholemia, the poisonous symptoms that develop have been referred by most authorities to the presence of biliary acids. Isotonic tension and increased resistance of the red blood cells are peculiar characteristics of red blood in jaundice. Bile acids affect the union of hemoglobin with the stroma of the red cell, rendering the hemoglobin more easily soluble, and this accounts for the solution of red cells in jaundice, as well as in other conditions. Icteric blood has also an increase in the nitrogenous bodies. Well marked cholemia may be detected by the inspection of serum or foam on heating to 50 degrees, I. C. Bilirubin may be changed to biliverdin by that process. In the rabbit, by the intravenous injection of glacial acetic acid, he had been able to get an acid reaction several hours afterward by the phenolphthalein test. The specific gravity of the blood is increased by sweating, by lack of food, muscular exertion; and it may be decreased by freely imbibing in water or fluids. Homberger found that albumins and chlorides behave differently after changing osmotic conditions. If a little acid is added to the blood, albumin and phosphates pass from red cells to the serum, while chlorides pass from serum to cells; but when alkalis are added the opposite conditions are induced.

In order that a satisfactory examination of the blood

might be made, the following things were requisite: Apparatus must be absolutely clean. The various stages of the process must be performed rapidly because the cell coagulation of the blood will interfere with any of the tests. The work must be done accurately. By making large quantities of the stain and keeping some in glass-stoppered bottles, will standardize the solution, so that one will receive the minimum variations in intensity of stain. Fixing a specimen by continuous heat, with as slight a degree in variation in distributing the heat as possible, is of value.

Dr. Thomas McCrae, of Baltimore, read a paper entitled "Pernicious Anemia: Report of a Series of Cases." In this he made the report of 40 cases that had occurred in the service of Dr. Osler, at the Johns Hopkins Hospital in a period during ten and eleven years. During the same time there were about 12,500 medical patients. Of the 40 patients, 32 were males, and 8 females. Two were colored. The ages varied from ten to seventy years, the largest number occurring in the fifth decade. As to the etiology, worry and mental strain were only present in 3 cases. Pregnancy was associated in 1. Oral sepsis was not invariably present in the recent cases. Among the symptoms, the most frequent were weakness, change of color, and loss in weight. The latter symptom occurred in more than one-half of the cases, and emaciation was marked in 10 cases. Pigmentation of the skin was found in 8, and petechiae in 4 instances. In the abdomen the liver was felt in 2 cases, and the spleen in 6, but in none was the enlargement at all marked. When the cases first came under observation, the hemoglobin averaged 30 per cent., the red cells 1,560,000, and leukocytes 6929 per cubic millimetre. Of the 16 cases, with a count below 1,000,000, only 4 recovered. The average differential count for 36 cases was: polymorphonuclears, 61%; small mononuclears, 31%; large mononuclears and transitionals, 4%; eosinophiles, 2%, and a fraction of 1 per cent. of myelocytes. The average number of nucleated reds per 1000 leukocytes was 37, of which 23 were normoblasts, 5 were megaloblasts, and 9 were intermediary forms. In a comparison of the fatal and the non-fatal cases, the average percentage of small normoblasts was rather higher in the cases that recovered, but the number of megaloblasts was eleven times greater in the fatal cases. There were nervous manifestations in 14 cases. These varied from slight disturbances only to complete paraplegia. It is not possible to group these cases under any division, as the symptoms were so varied. The prevailing type, however, was of a more or less spastic condition, with some inco-ordination and marked sensory disturbances. In some the nervous symptom seemed to vary with the state of the blood. As to diagnosis, the distinction from gastric cancer may be difficult. In this the higher count of the red cells usually found, the lower color index, lower percentage of small mononuclear and absence of megaloblasts are all important factors. Certain cases which show some features of splenic anemia are hard to place, of which 3 were cited. They had a prolonged course, marked enlarged spleen, ascites in 2, and the general blood conditions of pernicious anemia. They were not included in this series. The average duration of 17 fatal cases was 12 months. In 8 the course was under 6 months. One case recovered and came under observation 7 years later with cancer of the stomach, and one is in good condition 6 years after the onset. He summed up the treatment into rest, fresh air, good food and arsenic.

Dr. George Douglas Head, of Minneapolis, read a paper on "The Leukocyte Count in Hemorrhage." He desired to place on record some experimental work upon the leukocytes in hemorrhage which had given results somewhat different from the generally accepted views. In his experiments upon dogs the same law seems to govern the increase or decrease of leukocytes in the circulating blood as in man. Where there is a leukocytosis of digestion, or following septic infections, it is the same in dogs as in man. The variation of leukocytes in the circulating blood of man is the same as in dogs. In all probability the conclusions arrived at from his experiments in dogs, he thought, would apply equally well to the human beings. He formulated his results as follows: 1. In dogs a diminution in the number of white cells in the circulating blood immediately follows a profound hemorrhage. 2. This initial leukopenia is followed sooner or later by an increase in the number of leukocytes in the circulating blood. This is the so-called post-hemorrhagic leukocytosis of all writ-

ters. 3. This leukocytosis of hemorrhage continues for at least seven days, and, in some cases, much longer.

Dr. W. T. Higgins, of Courtland, N. Y., stated that Hunter's success in the treatment of this disease seemed to offer something in favor of his theory. He had treated every case on the lines laid down by Hunter with success. Asepsis of the mouth should not only be secured, but also of the upper air passages as well.

Dr. McCrae, of Baltimore, said that brilliant results had been obtained from the use of arsenic. In 1890 he had a case who is alive and well to-day. Another case he had treated returned six years after with cancer of the stomach. Cases he had seen get well when treated by arsenic, fresh air, good food, rest, Epsom salts and the employment of oral asepsis.

Dr. Heinrich Stern, of New York, read a paper on "Osmotic Pressure and its Relation to Uremic Manifestations." He believed that we were looking in the wrong direction when we tried to fasten the origin of uremia and kindred affections upon a purely physiologico-chemical basis. Most of the effete products *per se* were little toxic. Potassium seems to exert the greatest poisonous qualities. Urine, injected into the veins for experimental purposes, has shown that uremia is not the consequence of one, but of the retention of all those substances which normally enter into the composition of the urine. In the urine we do not encounter any other factors but those that are prevalent in the normal state. The only difference is the quantity. Uremia is, therefore, rather a physical than a chemical anomaly.

In referring to osmotic pressure in the body fluids he stated that all organic matter is saturated with water; that the cells of the body are more or less permeable for water. If the contents of the organism are soluble salts and remain unaltered in water, so that for a certain period neither salts nor water are introduced nor eliminated, all the watery constituents of the organism would become one homogenous liquid and the same osmotic pressure would prevail over the entire system. The molecules of a number of compounds, when dissolved, were divided up and dissected into "ions." The higher the dilution the more perfect the dissociation, as a rule. There is no vital process in which diffusion, or osmosis, does not participate. Conditions for the evolution of osmotic pressure always exist in the organism, for whenever two solutions come in contact by means of a semi-permeable wall, osmotic tension is displayed. When the excretory activity of the kidney is materially interfered with, the products of catabolism are retained in the blood. The great number of molecules dissolved in the plasma exert a high osmotic tension, and tend to diffundate (?) toward the less concentrated body liquids. Ultimately all the fluids of the body exhibit a similar degree of concentration, which is accompanied by a series of manifestations co-ordinate and successive, which have been grouped together under the term "uremia." This is really a mechanical intoxication, not one of chemical origin, but one due to an abnormal increase in osmotic tension of the blood plasma and the fluid of the body.

The phenomena which occur in the blood after the injection of large amounts of concentrated salt solution are the same as those which occur in uremia. They make their appearance together with the increase in the concentration of the blood, when the elimination of the accumulative qualities of the tissues does not occur any longer. Noss noticed in dogs tonic and clonic convulsions after intravenous injections of 10 per cent. sodium chloride solution, and, in such event, that the blood had attained twice its former concentration.

Dr. Charles G. Strocton, of Buffalo, N. Y., read a paper entitled "Circulatory Disturbances Accompanying Cirrhoses with Inoculation of the Portal Branches with Systemic Veins." Some practical conclusions could be drawn from the data given. The first of these, to which it would seem unnecessary to call attention, but that it appeared to have been somewhat overlooked, is that the normal osmotic pressure in the portal vein is low; that when it is suddenly raised, it is apt to be followed by symptoms of toxemia, and that these symptoms may be promptly relieved by purgation. A second important conclusion is that when the vascular changes, and the raised portal blood pressure that permit the passage of the portal blood into the systemic vein, are brought about gradually, the subject is better able to resist the toxemia, becoming, as it were, immunized to the offending portal blood, hence symptoms are less striking.

and with proper care as to diet and purgatives may be practically overcome.

Dr. Victor C. Vaughan, of Ann Arbor, Mich., made a few remarks on **Cirrhoses of the Liver** due to metallic poisons and said that lead and copper were the substances which should be considered so far as their effect upon the liver were concerned, and particularly upon the changes in the connective tissue of the liver. Alcohol is one of the most important factors in the production of the cirrhosis of Laënnec. Lead and copper generally, if not always, produce changes in the liver cells which are characterized by a fatty degeneration or fatty deposit in the liver cells. There had been considerable discussion as to whether the first changes take place in the hepatic cells or in the connective tissues. But so far as the metallic poisons were concerned he thought the changes in the liver cells were prior in time to the changes in the connective tissues. Certainly they are recognizable earlier than the other changes. He had seen a number of cases of cirrhosis of the liver due to lead poisoning. It is not often that we see cases in the early stages of liver changes at autopsy; therefore we must rely on animal experimentation in our endeavor to trace the relationship of these changes. In a number of cases of metallic poisoning there occurs subsequently an overgrowth in the connective tissue of the liver.

Dr. John H. Musser, of Philadelphia, spoke on the subject of **Treatment of Cirrhoses of the Liver**. He divided these cases of cirrhoses of the liver into (1) those in which no symptoms occurred during life, the cirrhoses having been found at autopsy, the patient dying from other causes; (2) those cases that were not suspected until such an accident as hemorrhage made it apparent, i. e., latent cirrhoses of the liver; (3) cases with the symptoms of portal obstruction and (4) on the other hand biliary obstruction. The lines of treatment were largely dietetic and hygienic, great care being taken to see that the functions of the gastrointestinal tract were kept in action and the renal secretions properly regulated, as well as the action of the skin. He raised a word of caution in regard to the presence of hemorrhoids. He had seen two or three deaths follow the operative treatment of hemorrhoids and, at the autopsy, cirrhoses of the liver was learned of for the first time. In all cases of hemorrhoidal disease a thorough knowledge of the state of the liver should be known before any operative interference is advised.

The treatment of ascites occurring in cirrhoses is today particularly interesting because of the recent attempts to cure this condition by operation. The speaker was accustomed to use mild purgation and calomel from time to time; he also used calomel in 1-40th of a grain dose, every three hours, as a diuretic. He also relied upon the old-fashioned pill digitalis, squills, and calomel. He also had considerable confidence in the use of the oil of copaiba. In any case of ascites he resorted to tapping early and frequently. The question of permanent drainage was then considered and he referred to a case that was operated upon by Dr. Frazer; the abdomen was opened, the peritoneum was scarified and the omentum attached. This was done 12 months ago and the patient is cured, there having been no recurrence.

Dr. Thomas D. Fletcher, of Baltimore, read a paper entitled **Cirrhoses with Pigmentation**. The association of pigmentation of the skin and tissues with a form of hypertrophic cirrhoses of the liver rather than with the atrophic form was emphasized, and he discussed at length the pigmentation associated with hypertrophic cirrhoses of the liver which occurs in the disease described by von Recklinghausen as "hemochromatosis." He also dwelt upon the source, chemical composition and distribution of the pigment. He endeavored to show that diabetic cirrhoses with bronzing of the skin, *diabete-bronze* was probably identical with von Recklinghausen's hemochromatosis. So far as he was aware but 4 cases of cirrhosis of the liver with general pigmentation (hemachromatosis) have been reported from this country.

Dr. James J. Walsh, of New York, read a paper entitled **Rheumatic Stimulants**, in which he stated there were three terms in medicine that had an indefinite signification—rheumatism, gout and catarrh, and curiously enough these terms are descriptive of the same idea. Acute rheumatic arthritis we have come to realize as being an acute infectious disease of microorganismal origin. Its very similar-

ity to gonorrheal rheumatism points strongly to the microbic origin of the disease. He referred to a series of joint symptoms that occurred in connection with certain toxemias. Observations were made pointing to the fact that there might be serious involvement of joint structures without there necessarily being any microbic metastasis. Painful affections around a joint point to two facts, (1) the nervous mechanism supplying joints, owing to its greater use than most of the other groups of nerves makes it extremely sensitive to disturbances of the circulation; (2) tissues in the neighborhood of joints being much used and subjected to injury are liable to take on chronic inflammatory conditions. In a series of cases occurring in the service of Professor Katzenbach at the New York Polyclinic certain observations were made. These cases presented painful symptoms which are usually referred to the neighborhood of joints and which have been diagnosed as rheumatism. When the patient was not able to give a straight history of acute rheumatism with red swollen joints, fever and sweating, the case was at once assumed not to be rheumatic in character and very seldom was it necessary to retract this assumption. Among 40 cases presented, 15 had so-called rheumatic symptoms of the lower limbs due to flat foot, and this proportion, a little more than one-third, represented very nearly the ratio in which flat foot symptoms are mistaken for rheumatism. Very often the symptoms are worse on rainy days or in damp weather, probably from the fact that on damp muddy days these patients are apt to wear old shoes which do not furnish good support to the arch of the foot. Again, the nerves are much more sensitive when there is dampness. In speaking of occupation neuroses he said that there was no occupation that involves a frequent repetition of muscular movements, but what might produce it. For instance, so simple an action as sweeping, if done as a regular occupation and constantly performed with a broom in the hand will, in individuals who are run down give rise to painful feelings, either in the shoulder if the broom is grasped too high up to enable the person to take advantage of the proper leverage in making the sweep, or in the leg if the body is constantly supported on one leg during the process of sweeping. The brachyalgia that occurs in connection with frequent and badly directed use of the small muscles of the forearm is well-known, occurring in telegraphers, in writers, in penmen, in typewriters, in piano players, etc., as a result of a sort of sympathy with the lower arm, and the shoulder often suffers from a decided ache, and it is surprising how often this ache is treated for rheumatism.

Dr. Charles Lyman Greene, of St. Paul, Minn., presented to the section **A Case of Acromegaly Presenting Certain Features of Unusual Interest**. The young man was 25 years of age and had had no fixed occupation but for some years prior to the development of the disease had spent the winter months on the ice, a point of some importance; inasmuch as the history of many of these cases has strongly suggested the influence of long exposure to cold and dampness as a predisposing or exciting cause. The family history was negative. Lues was denied. At five years of age he noticed a rapid enlargement of the hands and feet and the members of his family noticed a change in his physiognomy. The enlargement of the hands and feet steadily continued and progressed quite rapidly up to the time that he presented himself three years ago, when the hands and feet were found to be of enormous size. The wrists and ankles were free from inflammations, but were quite bulky, thick and in strong contrast with the forearms and legs. He complained of languor and weakness but has had none of the severer vertical pains so common in acromegaly nor did he complain of pain in the lumbar region of limbs. The senses and the nervous system were not disturbed. The skin was nearly normal and lacked the hardness of myxedema. The appearance of the face was especially interesting the skin being thickened and hypertrophied, though not rough. The upper and lower eyelids were thickened, and the ears appeared clumsy and tumid, as also did the nose. The nasal arch is prominent, the malar bones project and the lower jaw is apparently enlarged from the ankle to the symphysis and vertically. The enlargement of the upper jaw had no doubt masked the changes in the lower jaw, depriving the case of one of the so-called typical signs of the disease. The tongue is large, the larynx is enlarged and its cartilages appear to be the seat of hypertrophy. The radiograph demonstrated the remarkable en-

largement of the bones. The feet presented the same typical characteristics as the hands. There were no marked enlargements of the great toes. The hands and feet were not the seat of pain nor were their movements much restricted. A feature of especial importance is the marked increase in the bulk of the overlying tissues which present the appearance and sensation of a hard edema exactly like that of myxedema. The treatment had been solely by thyroid extract, the result being an immediate and marked amelioration of the disease.

The Election of Officers: For Chairman, Dr. Frank A. Jones, of Memphis, Tenn.; for Secretary, Dr. Robert B. Preble, of Chicago.

THIRD DAY, JUNE 6th, 1901.

Dr. T. B. Greenley, of Meadow Lawn, Tenn., read a paper on **The Modified Treatment of Typhoid Fever**, in which he advocated the use of acetanilid with quinine; acetanilid he claimed had soothing and quieting effect, and prevented the possible irritating effects of the quinine. No depressing effects of this drug upon the heart had ever occurred among his cases. The dose was increased or diminished according to the rise or fall of the temperature.

Dr. O. T. Osborne, of New Haven, Conn., read a paper entitled **Mental Shock**. He did not wish to appear as advocating the use of this term for conditions of failing heart due to distinct pathological conditions, or due to a gradual break-up in the system by very acute or prolonged intense processes: he thought the term was justifiable when a badly acting and gradually weakening heart was the most urgent cause for anxiety and its weakness was out of proportion to the pathological conditions or symptoms present. He believed that we were justified in using the term surgical shock. The symptoms were more or less rapid heart, irregular, perhaps dicrotic or intermittent pulse, incomplete respirations without much actual dyspnea, interspersed with frequent sighs, and the subjective symptoms of precordial oppression. The temperature was generally low, the flesh cool and clammy, if quick relief be not obtained, death will soon take place by heart failure or mental shock. He believed that mental shock was just as certainly a vaso-motor paralysis as is surgical shock, and as a consequence, the major part of the blood is to be found in the abdominal veins. The blood flows slowly into the dilated, and therefore non-elastic arterioles, hence slowly into the capillaries, and returning slowly in the veins and imperfectly fills the heart cavities. The heart contracts irregularly, incompletely, and arrhythmically. The aorta has not the pressure ahead or the forcible quota of blood from behind and consequently does not give enough elastic rebound to force blood properly into the coronary arteries, and the heart muscle is improperly nourished. By the lowered blood pressure the functions of the body begin to fall, all digestive processes are impaired and molecular death begins to take place. Severe acute nerve pain will, if continued, give a lowered vasomotor tension, and if too long continued or too severe, vasomotor paralysis or shock perfectly similar to that due to profound injuries of these nerves, or surgical shock. In acute feverish processes our aim should be to make the elimination at least equal to the production of the decomposing and fermenting products and to prevent the absorption of these products if possible. In all diseases and conditions there is a piling up in the blood of absorbed poisons, be they from typhoid fever, or dysenteric ulcers, from pus collections, from malarial plasmodia or hemoglobinuric debris, from cancerous disintegration, from unhealthy catarrhal, edematous mucous membranes, etc., any treatment which hastens the evacuation of the extreted bile impregnated with toxins, will prevent systemic and nervous poisoning, and ultimately vaso-motor disturbances and mental shock.

Dr. L. Napoleon Boston, of Philadelphia, read a paper on **Coughing as a Means of Disseminating Tubercle Bacilli: A Study of Fifty Cases**. The conditions which prompted him to investigate as to the degree with which tubercle bacilli were disseminated were first, that from the mouth of an inmate of the Philadelphia Hospital he noticed that fine droplets of sputum were ejected with each act of coughing, and second, that coughing was often excited by eating. He thought that this possibly explained why patients in the early stages of the disease did badly in this institution where every possible attention was given to ventilation, light and the disinfection of the sputum. The spray was collected by a mask, the essential features of

which were that it was made of German silver wire, one piece of which was moulded to fit the face, resting on the nose, cheeks and chin. To prevent irritation it was covered with rubber tubing. Suspended from this wire was a second oblong portion provided with two lateral grooves which served to accommodate two microscopic slides. When the mask was in position the slides were held in front of the mouth and nose at a point about three inches distant from the lips. The piece is held in position by an elastic band. The patients were allowed to wear this about an hour and only during that part of the day when they coughed the least, and they were instructed to remove it during attacks of coughing. Of the 59 specimens obtained from 50 patients, 38 were found to contain tubercle bacilli in variable numbers, four to six being the smallest found in any specimen. In 3 of the 12 negative cases the patients were so weak that they could hardly talk while wearing the mask. It was shown that the secretions of the mouth and respiratory tract are atomized and given off in the form of sprays, in both health and disease, and that this spray contains bacteria and other cellular elements known to be common to such secretions, and therefore it was rational to suppose that many other diseases were conveyed by this media, and that the work accomplished through the study of consumptives was but a step in a direction which bids fair to modify the hygiene of infection. Conditions affecting these organs and consequently their secretions must of necessity be spread in this way: especially was this true of diphtheria, tonsillitis, and possibly small-pox, measles, scarlet fever, whooping-cough, mumps, etc. Droplets alighting on clothing must serve as a favorable means of conveying the disease from house to house; and men may become infected by the spray projected by horses, cows, etc., and other domestic animals suffering from glanders, tuberculosis, and similar affections, and this appeared to be highly probable.

Dr. M. H. Fussell, of Philadelphia, presented a paper entitled **The Value of Throat Cultures in Diphtheria**, in which he said that the following could be proven: (1) True cases of diphtheria may have few or no clinical symptoms. (2) Cases of tonsillitis or pharyngitis may have severe symptoms and be serious, but no true diphtheria be present, or the presence of the Klebs-Loeffler bacillus, and consequently the patient was not able to transmit the disease. (3) A diphtheritic exudate may be easily detached and leave no bleeding surface. (4) An exudate due to some other organism may be true membrane, impossible to detach from the mucous membrane. He said that cultures can most surely and with less risk of mistake be made at the laboratories, but that they could be made at home, and that they should be made there if we intend to keep pace with the rapid strides of recent medicine.

Dr. Ferd. C. Valentine, of New York, presented a paper on **Genito-Urinary Examinations by the General Practitioner: With Demonstrations on Patient**. It was his desire to show (1) that all genito-urinary examinations should be painless: (2) the operator should conduct no examinations unless his arms were bared to above the elbows and his clothing protected by a gown and apron: (3) during every examination, the physician should protect his eyes with spectacles (not eye-glasses) even if he had no visual defects: (4) ideal examinations are made in the morning before the patient has passed his urine: (5) the amount and character of a urethral discharge can be estimated only by correct technique in expressing the urethral contents: (6) the color of the urethral discharge changes when it dries upon the patient's garments: (7) the meatus should be cleaned before passing urine for examination: (8) the manner of urinating is often pathognomonic: (9) the epithelium found in the urine is indicative of the locality of the lesion: (10) examination of the urethral adnexa is a necessary part of the steps for complete diagnosis: (11) no instrumental ingression of the urethra should be attempted without most thorough efforts at rendering it aseptic: (12) the technique of striving at urethral asepsis is neither complicating nor difficult: (13) the soft bougie-à-boule is the only instrument that can be used for tactile exploration of the urethra: it is purely a diagnostic instrument: the rigid sound is wholly a therapeutic instrument: (14) urethroscopy with a modern instrument is not difficult: (15) the general practitioner is perfectly competent to examine the vast majority of genito-urinary cases: (16) such examinations only exceptionally require extra-ordinary skill or a large armamentarium: (17) the

pathology of genito-urinary diseases in no wise differs from that of other affections.

Dr. Frank Billings, of Chicago, read a paper on **Clinical Observations in Pericarditis**, in which he stated that pericarditis is essentially a secondary process occurring in the course of some general infection. The local manifestations may be so slight as to escape observation and the general symptoms to which the local disease may give rise may be obscured by the constitutional disturbance of the primary general infections. Therefore it often happens that the diagnosis of pericarditis is more often made at autopsy than clinically. The histories of several cases were given which presented clinically, as far as the heart and pericardium were concerned, practically the same signs and symptoms. The cases further illustrated the importance of the three cardinal signs of pericarditis, namely, the pericardial friction rub, the form of outline of the pericardial dullness, and the position of the apex beat especially in relation to the left border of pericardial dullness. In every case the pericardial friction rub is doubtless present in some period of its course. It is practically the sole local sign in plastic pericarditis. In pericarditis with effusion it may not be recognized, although it is probably present in every case at an early stage of the disease, and in cases of recovery after the disappearance of the effusion; it may be present too during the stage of effusion. The form of this outline of dullness in pericardial effusion is also characteristic. The pear-shaped outline with the base downward; the dullness, even in the early stage of effusion, in the fifth right interspace close to the sternum, obliterating the resonant angle formed by the lung, heart and liver; the dullness over the sternum extending to or above the second rib, together with the outline of the left border dullness are easily recognized and are almost pathognomonic. It is also true that a greatly enlarged heart with all the chambers dilated from myocarditis and a weak diffusible apex beat may present an outline of dullness which so nearly resembles that of pericarditis with effusion that it may be impossible to differentiate between them without puncture. The location of the apex beat in pericarditis with effusion is characteristic. It will always be found, when it is perceptible, that the left border of dullness is relatively far removed from it as it is not in any other cardia disease. It may be obscured, in large effusions, and at other times the right ventricle may strike the chest wall in the region of the nipple, or undulatory waves may be seen as the only evidence of the heart beat against the chest wall. However, it matters not how the apex beat or the impulse of some other part of the heart against the chest wall be ascertained it will be found that the point of contact of the heart against the chest wall is always relatively far removed from the left border of precordial dullness as compared with the relations of the apex beat to the left border dullness in all other conditions. The signs of compression of the left lung evinced by the left subscapular dullness and bronchial breathing, the relatively rapid respiration and dyspnea, the rapid heart action, the pulsus paradoxus and the asymmetry in size of the pulse of the radials, the irregular type of temperature, the paralysis of the left recurrent laryngeal nerve, the unequal pupils, the disturbed mental state of the patient and still other phenomena are signs and symptoms not so characteristic as the three cardinal signs first named, but are important and significant when present. Frequent careful systematic examination of the precordium should be made in all infectious diseases, and if this is done by the clinician pericarditis will not escape him. Pericarditis is an easily recognized condition.

Pathology and Pathogenesis of pericarditis. This paper was read by Dr. Jos. McFarland, of Philadelphia. He said that it is more frequent in men than in women, probably because they were more exposed to its causes. It is customary to divide the cases into those which are primary or idiopathic and those which are secondary or metastatic. Concerning the relative frequency authors vary. Traumatism as a cause of pericarditis is of importance only as it affords an avenue of entrance for micro-organisms, or produces conditions favorable to their colonization in the tissues. Lymphogenous metastasis may occur in many of the local affections in which no actual traumatic lesions existed. In this manner disease of the mediastinum, pleura, etc., may occasion pericarditis. Hematogenous metastasis is seen in nearly all of the infectious diseases,

but especially in rheumatism, pyemia, septicemia, pneumonia, chorea, scarlatina, etc. There is no specific micro-organism of the pericarditis. Breitung collected 324 cases of pericarditis among the autopsies of the Berlin Charité between the years 1866 and 1876 and found them distributed as follows: Pericarditis sero-fibrenosa, 108; pericarditis hemorrhagia, 30; pericarditis purulenta, 24; pericarditis tuberculosa denteropathia, 24; pericarditis tuberculosa idiopathica, 2 pericarditis adhesiva partialis, 111; pericarditis adhesiva totalis, 23; pericarditis ossificans, 2. It is an error to think of these names as referring to distinct forms of the disease; they are for the most part stages of the same process. In 39 cases studied by Louis the exudations were serous, 9; purulent, 7; sero-sanguinolent, 10; sero-purulent, 13.

The effect upon the heart of pericarditis is of great importance; no considerable disease of the epicardium is possible without involvement of the heart. The superficial layers of muscular fibres usually show cloudy swelling, later, hyaline or fatty degeneration. The pus may also gradually work its way between the muscular bundles, in cases with purulent exudate. The changes that thus take place during the height of the disease predisposes to acute dilatation of the heart and a fatal termination of the disease may thus be brought about. If this does not occur and if the patient recovers from the pericarditis, the regenerative cicatricial processes that go on lead to fibroid interstitial changes in the wall of the heart.

Robert B. Preble, of Chicago, read a paper on **The General Etiology of Pericarditis**. He made the following conclusions:

1. Cases of acute pericarditis, clinically primary occur, but are rare.
2. Diseases to which pericarditis appears as a complication are in order of their frequency; pneumonias, 34%; rheumatism, 23.36%; chronic diffuse nephritis, 11.2%; tuberculosis, 10%; sepsis, 4.7%; aneurysm, 2.6%; typhoid, 1.7%.
3. The more extensive a pneumonia, the greater the danger of this complication.
4. The danger is somewhat greater with left than with right side pneumonia.
5. Where only one lobe is involved, the danger is least with a right upper lobed pneumonia and greatest with a right middle or left upper lobed pneumonia.
6. With a unilobar pneumonia, the changes of a pericarditis are one in forty, with a bilobar or trilobar, one in ten, with a quadrilobar, one in five and with a pneumonia of the entire left lung, one in eight.
7. The mortality of pneumonias with pericarditis is 92.4%.
8. Rheumatic pericarditis is complicated by endocarditis in 60% of the cases, i. e., three to four times the normal rate of cases of endocarditis.
9. The danger of pericarditis complicating rheumatism is the greater the younger the individual, and is somewhat greater with males than with females.
10. So far as acute pericarditis is concerned, the site and extent of the endocarditis is apparently of no importance.
11. Pericarditis appears as a complication of all forms of nephritis, but particularly the chronic diffuse nephritis with contraction.
12. It is an extremely ominous thing, for 22, i. e., 84.6% of the cases died.
13. It is still uncertain whether the pericarditis is toxic or infectious.
14. Tuberculosis excites only 1-10 of the cases, and when one considers the extreme frequency of tuberculosis pericarditis must be regarded as a rare complication.
15. Pericarditis may be a part of a generalized acute tuberculosis, but is more often the result of a chronic tuberculosis of the lungs or mediastinal glands.
16. Septicemia and pyemia contribute a very considerable number of cases of pericarditis. The primary focus may be remote or close to the pericardium.
17. Aneurysm of the aorta causes 2.6% of all the cases, a very high figure, when one recalls the comparative infrequency of aneurysm.
18. Typhoid fever, which is rarely complicated by inflammation of the serous membranes, other than the peritoneum, contributed 4 cases, which is 1.7%.
19. The cases of obliteration of the pericardium are due to the following causes arranged in order of importance: endocarditis, tuberculosis, chronic nephritis, aneurysm.
20. More than one-half of the cases, in which the cause was clear, were due to endocarditis, or rather to some cause common to both the endocarditis and the pericarditis, and more than one half of these cases showed a combined aortic and mitral endocarditis.
21. Relatively six times as many cases of obliteration of the pericardium occur with aortic and mitral endocarditis than with either lesion single.
22. Tuberculosis causes but few cases of obliterative pericarditis.
23. Pericarditis, accompanying nephritis is

not always fatal, but may apparently end in the formation of adhesions.

A paper on **Adherent Pericardium** was given by Robert E. Babcock, of Chicago, in which he stated that adherent pericardium was encountered in two forms, first in which adhesions between the two layers of the sac, but not of the pericardium to the surrounding parts, pericarditis interna; and second, the pericardium adherent to the epicardium and also to the neighboring structures, pericarditis interna et externa. He then considered the effects on the heart and general circulation, with special consideration of its effect on the liver, leading to the so-called pseudotrophic cirrhoses of the liver. Diagnosis, in the first form mentioned was usually very difficult and often impossible. He then made a cursory examination of signs. If the adhesions are limited to the two layers of the sac, and if they are unassociated with valvular diseases, the result may be only hypertrophy of the heart, and the circulation will be carried on adequately and no subjective symptoms are produced. If pericarditis leads to adhesions while the heart is in dilatation from endocarditis, then the heart is prevented from ultimately returning to its previous size and the symptoms are likely to occur, viz.: those to stasis. In the second form mentioned the diagnosis was often easy in consequence of the signs resulting from the pulling of the adhesions upon the surrounding soft parts.

Tuberculous Pericarditis. C. F. McGahan, of Aikin, S. C., read this paper, in which he stated that this disease was much more prevalent than had heretofore been generally accepted. He believed that a great many cases of obscure heart troubles occurring in the anemic when we could find no valvular disease without marked symptoms of pericarditis, but where we have certain marked symptoms of the disease, is due to tubercular pericarditis, particularly if later the patient begins to lose weight and assume a cachectic appearance. This condition usually progresses insidiously, and he believed that it was communicated to the pericardium through the lymphatics, arterial and venous systems, and from all that tends to cause tubercular troubles in the peritoneum. The symptoms of tubercular pericarditis are those that we would get from enlarged heart, together with the general symptoms of malaise, and more disturbances of the general system that could be found in a simple pericarditis, or that secondary to rheumatism, or one of the exanthematous diseases.

Cardiac Lesions as Observed in the Negro; with Special Reference to Pericarditis. This paper was read by Frank A. Jones, of Memphis Tenn. He made the following recapitulation: (1) Aortic regurgitation in the negro was the most frequent and most dangerous of all valvular lesions. (2) The most frequent, aortic stenosis. (3) The next, mitral regurgitation. (4) Mitral stenosis had not been diagnosed in the cases he reported from the physical signs and symptoms. (5) Tuberculosis and syphilis acted both as exciting and predisposing causes in the production of muscular and valvular lesions. (6) Syphilitic history in mitral regurgitation was more frequently found than that of rheumatic. (7) The murmur of aortic regurgitation was most frequently musical.

Some Points in the Treatment of Pericarditis. Frank Parsons Norbury, of Jacksonville, Ind., said that it behooved us in the treatment of rheumatism, acute infectious fevers and septic processes to keep ever in mind the possibility of pericarditis as an aftermath and govern ourselves accordingly by insisting upon absolute rest and quiet until this danger is past. Each case must be treated upon its individual merits. Quiet surroundings and rest must be enforced; this is important because it "curbs the symptoms and places the patient under the most favorable condition for speedy recovery." Milk is the most suitable diet. It should be given in small quantities every two or three hours. It is well to remember that most all cases of rheumatic pericarditis get well, if we will let them alone; keep them at rest and carefully meet indications as they arise. A blister over the pericardium will be sufficient for the relief of pain, or if it continues, cold applications, cold cloths, or an ice bag used as needed. When other means fail morphine should be given, guarding it with proper cardiac support. For the restlessness he preferred bromide of soda given usually during the day, usually commencing about noon, again at four in the afternoon, and at bed time. For the sleep he used trional. If combined with sulphonal its effects are prolonged. For the cardiac distress strychnine may be given or, if neces-

sary, digitalis with strophantus. To properly care for the effusion is one of the prime essentials of treatment. If moderate, unless septic, it will be absorbed, and even if large, the chances are that with cautious use of diuretics and purgatives it will disappear. The indications for surgical interference are, according to Osler, "dyspnea, small, rapid pulse, dusky anxious countenance," and we will add the physical signs of extensive effusion. The aspirator was recommended.

PRACTICE OF MEDICINE, HYGIENE, AND SANITARY SCIENCE.

JOINT SESSION, JUNE 7th.

Dr. T. J. Happell, of Trenton, Tenn., read an interesting paper on "**Further Report on Pseudo or Modified Smallpox.**" At the Atlantic City meeting of the Association last year he reported to the Section his experience with 300 cases of pseudo, or modified smallpox, which he had made from a bedside study of the cases in all stages of the disease. This paper dwelt upon some of the anomalies met with in 400 cases that had recently come under his observation. In many cases the disease was not communicable. Many persons that had been vaccinated had the disease, while many that had not been vaccinated escaped the disease. He considered the diagnostic points between this epidemic that occurred in Gibson county, Tenn., and variola vera of the writer's prior to 1895. He asked whether this could be called variola vera, or was it a hybrid? He presented the following differential points for the consideration of the Section: In the modified form there did not appear to be any prevailing types of the disease; they had the same general character, differing in degree only: the incubation was from fourteen to eighteen days. In smallpox, the types were varioloid, discrete, hemorrhagic and confluent, and the incubation period was from fourteen days to twenty-one days.

Symptoms—From the first to the third day.—In the modified form at the onset the patient complained of cold; they felt as though an attack of grippe or tonsillitis was coming on. Temperature 102-105. Little or no vomiting. Pulse rapid and full. Little or no prostration. No delirium. No convulsions in the young. In a few cases there may be sleeplessness. In smallpox the onset is sudden, with violent chill, persistent vomiting, agonizing pains in the back and limbs and head. Temperature 103-104. Pulse full, strong and rapid. Prostration great from the onset. Eyes injected. Sleeplessness, delirium and convulsions in the young. **Third Day.**—In modified smallpox, no coarse red spots appear. In smallpox, coarse red spots appear on the lips and forehead. With the appearance of these spots the temperature falls to the normal and the patient is comfortable. **Fourth Day.**—In the modified form the eruption appears, whose character is generally that of an acne. In some instances the shop-like papules appear, but it is rare. The temperature falls to the normal and the patient invariably gets up, if he has gone to bed, and he states that he is well. The eruption first appears on the face. In most about the forehead, cheeks and chin. In women and children irregularly about the face. There is usually a sore throat. In smallpox the small red spots appear on the forehead at the juncture of the hair, and is followed by their appearance on the extremities. Papules follow the red spots. They have a shot-like feel. **Fifth Day.**—In the modified form the acne-like eruption develops into vesicles which assume an opalescence at once. These vesicles are unicellular and are not umbilicated. The serum which exudes at their apices dries and turns brown, which, in some cases, gives them the appearance of umbilication. There is no puckering of the vesicle at its border. The temperature is generally normal unless it arises from abscesses or other causes. The vesicle may dry up and the disease may be then said to have aborted. A rapid recovery follows. In smallpox papules appear on the wrists and forehead. **Sixth to the Ninth Day.**—In the modified form the vesicle becomes filled with an opaque lymphoid fluid; in some cases with a brown nucleus in the center, which gives it an umbilicated appearance. This vesicle with its opaque fluid, mis-called pus, shrinks to $\frac{1}{4}$ its diameter and becomes a thin brown scab, perfectly circular. There is no stench. The patient is well after the appearance of the eruption, and insists upon getting up and having plenty to eat. If the eruption is copious he looks bad but he will tell you that he is all right and feels

good. The eruption in a few cases affects the conjunctivae. There is no secondary fever. From this time on it is simply a matter of scabs falling off. By the tenth day the patient is entirely well. If the eruption spreads over the entire body he may not be clear from scabs until the fourteenth day. In true smallpox the vesicles appear in place of the papules, and the eruption spreads gradually over the entire body. The vesicles are umbilicated and multilocular. On the 8th and 9th days the vesicles become pustular, and each is surrounded with broad, red bands, or efflorescence, the features become distorted, there are several rigors and fever, the original symptoms appear, stench is beginning, etc. There is great delirium and convulsions in the young. This is the critical period.

Tenth to Twelfth Day.—In smallpox the pus oozes and forms scabs, and the stench is particularly bad. **Seventeenth to the Twenty-first Day.**—In smallpox the scabs drop off, leaving red glistening pits which soon become white. Ulceration is deep, reaching the corium. Ophthalmia is generally present. Pustules pervade the mouth, larynx, pharynx and trachea. Petechiae form on the lower part of the abdomen and inner aspects of the thighs on the first and second days in some cases. **Papules.**—In the modified form papules, when present, are the same size as in smallpox, perhaps a little smaller, but fewer in extent. There may be no papules. Vesicles range in size from the head of a pin to the size of a split pea. They are not umbilicated, and, when punctured, collapse. The vesicle is unilocular. Convalescence begins on the appearance of the eruption. The so-called pustule does not extend into the derma. The epidermis is the only structure of the skin involved: there is, hence, no pitting. The vaccinated take the disease. In smallpox the pustules are about the size of No. 4 shot and have a translucent appearance, encroaching on the entire body, including the palms and soles. It appears first on the face and hands. Vesicles are umbilicated and multilocular. So is the pustule, and neither will collapse in toto if pricked with the needle.

..Dr. W. L. Beebe, of St. Cloud, Minn., read a paper entitled "The Old and the New." He said that he had been identified with two epidemics (20 years apart), and though they were evidently both species of smallpox, they were dissimilar in many characteristics. He thought that many of the recent cases of smallpox had been diagnosticated chickenpox.

..Dr. Louis Leroy, of Nashville, Tenn., read a paper on "Remarks Covering the Sanitary Features of Smallpox." In the event of an outbreak, he said that a competent physician should be placed in charge and given absolute power to act; he should communicate with Boards of Health; he should have police backing if necessary. Daily official reports should be made to the newspapers, stating the exact condition of affairs. Smallpox treated in private, he considered a makeshift; complete and perfect isolation he insisted upon. All articles should be disinfected in the usual manner; everything possible should be destroyed by fire after the patient had been discharged as cured.

In Tennessee this year he had introduced on a large scale the hypodermic needle as a means of vaccinating. He had first tried this method in Philadelphia in 1895, using then the aqueous solution he now uses in glycerinated lymph. A solid piston needle was used. The skin was cleansed in the customary manner and the needle inserted into the skin, not through it, and a drop of the lymph was forced between the epithelial cells and it diffused at exactly the locality required. It had many advantages; in cases of compulsory vaccination it cannot be washed off; there is absolute freedom from infection at the time of vaccination; it is painless and no immediate dressing is necessary.

..Dr. Heman Spalding, of Chicago, read a paper on "The Diagnosis of Mild Smallpox as in the Present Outbreak of the Smallpox in This Country." On February 15th, 1899, smallpox was introduced into Chicago from Cincinnati; in the 17 months following there had been 72 cases; 25 of these from direct importation. For a period of 3½ months the city was entirely freed from the disease. Then another outbreak occurred. These two outbreaks gave him an opportunity of studying 310 cases in Chicago in the Isolation Hospital.

1 hemorrhagic case	died	1
13 confluent cases	died	3
24 semi-confluent cases	died	2
54 severe discrete cases	died	0
179 mild discrete cases	died	0
39 modified form of cases	died	0
310 cases	died	6

He did not think the term varioloid should be used; many persons were under the impression that varioloid was not smallpox, and think that if they are taken to a hospital while sick with the former they will contract the latter disease. It was a useless term and should be discarded. In Chicago they placed all patient, whether afflicted with hemorrhagic, confluent, or so mild that they would go to work unless prevented, into the same wards in the hospital. 271 of the cases reported had never been vaccinated. None of those afflicted with the mild form of disease contracted smallpox from the severer typical cases in the wards where the exposure had been long and certain. The mild form of the disease gives immunity from smallpox and yet will transmit typical confluent, or hemorrhagic, smallpox, of which he had abundant proof in Chicago.

Dr. Frederick Leavitt, of St. Paul, Minn., read a paper on "The Distinguishing Characteristics Between Mild Discrete Smallpox and Chickenpox," in which he made the following summary:

	SMALLPOX.	CHICKENPOX.
Age.	Any age.	Childhood.
Incubation.	Two Weeks.	13-17 days.
Invasion.	Marked headache, backache, fever, general malaise, lasting 3-4 days.	Is none, or at most only slight indisposition.
Surfaces attacked.	Worse on the exposed parts extremities. Invariably on the palms.	Worse on the covered portions—thorax; rarely or never seen on the palms and soles.
Character of the eruption.	Progressive; papules, vesicles, pustules, crusts.	Papules and crusts. Lesion very superficial. Easy to rupture.
Histology.	Lesion includes the lower layers of the derma. Hard to rupture. Multilocular.	Unilocular.
Temperature.	Remains high (103-105) till the eruption appears; then it drops and does not rise again for a week, and not then in mild discrete forms.	Rises with the severity of the attack.
Contour of eruption.	Quite uniform in size. Has a reddened area at base. Frequently umbilicated.	Not uniform. Also inflamed area about the vesicle, but less marked.
Sensation.	Painful to the touch; it may itch.	Not painful to touch.
Duration, including period of invasion and desquamation.	Two to four weeks.	Seven to fourteen days.
Vaccination.	Protects.	Does not protect.
Pitting.	When confluent on face will occasionally mark in the discrete form.	Seldom unless infected.
Complications.	Generally none.	None.
Mortality.	High in severe confluent and hemorrhagic types.	Nil
Resolution.	By crisis.	By lysis.

..Dr. H. M. Bracken, of St. Paul, read a paper on "Variola," in which he stated that Minnesota had reported 7211 cases of variola with 49 reported deaths during the past two-and-a-half years. He did not think we could be governed in our diagnosis of all cases in this present epidemic by the usual text-book description of variola. Typical prodromal symptoms may be present, but the rash may vary in degree, in form, in type of progress, and in final disappearance in a way that is described in but few text-books. He asked if vaccination protected against

the disease. Of 662 cases in 244 houses, but 10 patients had been vaccinated successfully at any time prior to their infection, and of these 10, over 30 years had elapsed since successful vaccination for 2 of them, over 25 years for 4 of them, 20 years for 1 of them, and 6 years for 1. The Chicago Board of Health made the following statement: "Out of a total of 171 cases of smallpox found in Chicago between November 30th and April 10th, 1901, 140 had never been vaccinated. Of the remaining 31 cases, 29 were in adults showing faint, poor or irregular scars, claimed to be evidences of attempted vaccination in infancy or childhood—the most recent being 23 years old. Only 2 out of the 171 cases exhibited scars of successful vaccination." Since vaccination had been made compulsory in the schools of Chicago, smallpox had disappeared from them. The degree of immunity depends upon, in part at least, the intensity of the infection. Marson gave a death-rate as follows among those who have been vaccinated: One cicatrix 7.73 per cent.; two cicatrices, 4.7 per cent.; three cicatrices, 1.95 per cent.; four or more cicatrices, .55 per cent.

SECTION ON SURGERY AND ANATOMY.

FIRST DAY, JUNE 4th, 1901.

Dr. A. J. Oschner read a paper entitled, "Cause of Diffuse Peritonitis Complicating Appendicitis and Its Prevention." The author reviewed the anatomical and pathological relationship existing between the appendix and the adjacent organs. He showed how the appendix was protected and pointed out the enormous blood-supply of the omentum. The value of rest as a preventive to the extension of infection in any part of the body cannot be overestimated, and if this is gained another point is secured in the right direction. Infection of the general peritoneal cavity is caused by disturbance of the intestines. Theoretically and practically food and cathartics should not be taken into the stomach. The doctor cited cases in which the ingestion of these products greatly irritated the condition. His mortality in cases of perforative peritonitis was less than $\frac{1}{4}$ as high as cases operated at once; in cases of diffuse peritonitis there has been a great decrease. From January 1898 to May 1901 he had operated 565 cases of appendicitis with 20 deaths, a mortality of $3\frac{1}{2}$ per cent. Danger of rupture of the circumscribed abscess into the general peritoneal cavity has been a cause of great anxiety. There is increased safety in operating during the quiescent state and as a result of this treatment fecal fistulae never result. The doctor advocated gastric lavage, in cases of food in the stomach or intestines, above the ileo-cecal valve. The laity should be taught to stop feeding and giving cathartics to patients suffering from intra-abdominal diseases. Dr. Andrew McCosh read a paper on "Remarks on the Surgery of the Spinal Cord, with Illustrative Cases." He was of the opinion that pressure on the cord was urgent reason for operating and that early operations are important. He likewise believed that it was wiser to do the exploratory operation, because there the danger was slight. It was the routine practice to cut down on the skull to find out if there was fracture. If relief is to be expected, operation should be done at once. He had performed six laminectomies, two recovered and four died, but not as a direct result of operation. He did not think it was incumbent to apply any special support to the spinal cord. "Spina Bifida with Report of an Interesting Case," was the theme of Dr. Paul E. Eve's paper. Associated with spina bifida are hydrocephalus, talipes and hare-lip; it may consist of a tumor varying in size from a marble to an adult's head, occupying the central portion of the canal over the posterior aspect of the vertebral column. There are three varieties of this disease, namely-meningocele, the protrusion consisting of fluid in the spinal cord; meningo-myoele, where there is a portion of the cord in the sac, and syringo-myoele, the central part of the spinal cord being dilated. Various remedial measures were suggested, such as acupuncture, injection of iodide of potassium, etc. Extirpation is unjustifiable in young infants, and the indications for operation are where the child is over 7 years old and where the tumor was rapid in growth and rapidly threatened. The subject of Dr. Christian Fenger's paper was "The Methodical Exploration of the Brain for Fluid." The doctor described a case having a previous history of suppurating disease of the ear, an attack of appendicitis subsequently, of short duration and then swelling of the

elbow joint. He explored the brain methodically, going from one place to another. There was a cicatrix behind the ear, which was the only guiding point. After exploring the brain on the affected side of the head with no results, he then tried the opposite side, where the pus was found, and the patient recovered. The doctor said that methodical exploration of the brain was preferable to all others. Function, he said, was harmless, as Spitzka had previously proved in the needle-tracings in the brain which were aseptic. The author illustrated his paper with photographs, instruments and human skulls. The contribution of Dr. D. S. Fairchild, on "The Immediate and Remote Effects of Brain Injury" dealt with the value of first symptoms in determining the nature and extent of the lesion; the bearing on the question of treatment and prognosis; the possibility of the lesion being more or less serious than is indicated by the apparent gravity of the early symptoms; the danger of being misled on these points; the remote effects of trauma on the integrity of the brain-tissue in producing epilepsy and mental impairment; falls from a height or from a rapidly moving train. If the first symptom of intracranial hemorrhage is rupture of the middle meningeal, the immediate effect thereof is considered serious, unless surgery intervenes. The doctor reviewed scar proliferation from scars of the brain and said that these cases were amenable to surgical treatment. He presented the question of liability and medico-legal aspect of cases of brain injury. Dr. Frazier, Philadelphia, presented a contribution on the subject of operation for the relief of tic douloureux, or trifacial neuralgia, differing from the operations now in vogue, in that it depends for its success on the division of the sensory root of the ganglion and not upon the removal of the ganglion itself. The doctor very interestingly covered the besetting difficulties with which the surgeon meets, the technic of the operation and its applicability in present cases.

Discussion: Dr. W. W. Keen believed the time had come when cases of spina bifida should be submitted to operative treatment. In relation to Dr. Fenger's paper, he was sorry that he limited the exploration to search for pus, that there should be a very clear distinction made in exploring the brain for pus, purulent matter or serum. Ten years ago he had proposed a methodical operation and formulated several routes by which the ventricles could be reached. Dr. Keen cited interesting cases of exploring the brain for fluid. As to Dr. Fairchild's paper, he thought the doctor had taken the right ground, that interference was imperative. He reviewed the phenomena of the state of unconsciousness produced by trauma.

Dr. McLean agreed with Dr. Fairchild's idea of going without support; he had found it difficult to keep the support on; he thought it was a good step in spina bifida (Dr. Eve's paper) to attempt closure at operation, without aspirating or injecting fluid. He believed the skull was elastic and compressible in both young and adult, as was proved by clamping it; the tissue within must change and there must be movement within. The spinal canal is not a bony canal, but made up partially of fibrous tissue. The doctor referred to concussion and compression of the brain and subsequent extra-dural, subdural and cranial hemorrhage. "Now, I think, there is another point, where you might have depression of the skull. In that case the cerebral fluid will escape from the cranium, lessen the cranial tension and escape in the spinal cord. Doctor Weir did not believe that we had yet arrived at a conclusion with regard to depressed fractures of the skull without symptoms. In regard to wounds of the scalp, he had recently changed his ideas—he did not now let them alone. Surgeons feared, in penetrating the dura, making adhesions; adhesions must be expected; the discussor advocated the use of celluloid plates at the time of operation or at a secondary operation. Dr. Frank had tapped the lateral ventricles as early as 1890, with good results. He did not agree with Dr. McLean, that if a person was hit on the head it would draw the fluid into the spinal column, but it is not necessary to receive a blow on the head to become unconscious or give symptoms of concussion. Doctor Earl was of the opinion that the time was at hand when surgical treatment for injuries of the skull must be employed. Dr. Moore believed in the surgical treatment of spina bifida rather than the injections. Dr. Dawbarn related an interesting case of a man who was struck on the side of the head, with symptoms of hemiplegia. Operating on the paralyzed there could not be detected a clot or anything abnormal. At the autopsy, however, it was found that the

to that affected, there was revealed an enormous blood clot. Others who joined in the discussion were Drs. Bernays, Maxwell, Means, Crile, Tagart, McKnight, Baldwin and Vaughan, St. Louis.

SECOND DAY, JUNE 5th, 1901.

Paper by **Dr. John B. Deaver** (Philadelphia): "**The Mortality of Appendicitis.**" Dr. Deaver began by saying that during the year 1900 there were reported at the German Hospital in Philadelphia 268 cases of appendicitis, of which 144 were acute attacks of the disease and 124 were chronic. Of those operated during the acute stage 26 died or from some intercurrent illness arising during the illness or previously existing. In the cases not subjected to surgical treatment by far the largest factor is septic peritonitis. As to the number of attacks, the doctor said, that the fatal attack may be the "solitary severe one." "Severe attacks without fatal issue subside to varying degrees, but commonly render the internal symptoms more aggravated." In cases complicated with adhesions, but without septic infection, the mortality is very low. In one case the doctor operated 12 hours after the onset of the attack and found an advanced general purulent peritonitis, a condition from which I have never seen a recovery, and believed that where there is located pus the success of the operation depends upon the success in emptying and draining every pocket; merely opening and draining the main abscess will not do, the great problem being how to drain all these collections without infecting the general peritoneal cavity. Post-caecal collections of pus offer a serious problem. As to the advisability of removing the appendix in the presence of pus, the opinion of the author was that it should be removed, except in certain cases. Another very common cause of death is necrosis of the bowel. Dr. Deaver's experience showed that recurrent attacks of appendicitis are progressive in their severity, each one adding fuel to the flame; that the position of the appendix was an important feature; that delay in operating is responsible for more deaths in appendicitis than all the factors which have to do with the disease; that operation in the first 12, and at the latest 18 to 24 hours, would save patients, without subsequent complications, as fecal fistula, etc. On every case of appendicitis that dies in the German Hospital, there is made an autopsy. Paper by **Dr. Ernest LaPlace** (Philadelphia): "**Some Unusual Features of Appendicitis and Their Treatment.**" The doctor said that, as on a former occasion, he would repeat a statement: "In every case of fatal appendicitis, there was a time when, had the operation been performed, the patient would have survived. He was of the opinion that it was not the appendicitis that killed, but the peritonitis incident thereto. He divided the appendicitis into three different periods or stages: (1) That of appendicitis; (2) That of peritonitis; (3) That of septicemia. He believed in rapid operative procedure in peritonitis from chronic appendiceal abscess that has perforated or an acute peritonitis set up by appendicitis. Careful cleansing of the operative field should be instituted, with flushing of the abdominal cavity. When septicemia and peritonitis are both present, then simply wash out the abdominal cavity, close, and drain with gauze. He believed that it must be taken for granted that the phagocytes will compete more successfully with a slight amount of septicemia than with septicemia which is continually increasing by constantly forming toxins taken up from the peritonitis. Flushing continually the peritoneal cavity for at least a few hours after the operation would constitute the local treatment, whereby the arrest of progressive septicemia may be hoped for. Dr. Homer Gage, of Worcester, Mass., was detained by illness. The subject of his paper was: "**Abdominal Contusions Associated with Rupture of the Intestine.**" Dr. F. Gregory Connell (Chicago) read a paper entitled, "**The Knot Within the Lumen in Intestinal Surgery with Report of Eight Cases.**" The doctor said that the possibility of placing all the knots in enterorrhaphy within the lumen is no longer in doubt, but the advisability of such a procedure is still a disputed question by those who never used it. Perforation of all coats, when the knot is placed within the lumen, are not the same. The doctor said that death, in no case, can be attributed either to the method of suture employed or the manner of employing it; to include all the coats of the bowel-wall removes the danger of stitch yielding, that to fail to include the seromuscular layers an insecure stitch; that it is not only possible, but practical to place all the knots of an enterorrhaphy of the lumen.

Paper by **Dr. Roswell Park**, Buffalo, N. Y., "**The Nature of the Cancerous Process.**" "Like a huge and frowning sphinx at the very gateway or entrance to the field of surgical pathology has stood for centuries the great problem of the nature of cancer. This has, at least until recently, remained the inscrutable mystery of ages." The doctor reviewed Cohnheim's theory, and said that the parasitic or infectious theory of cancer is the only one which satisfies the needs of both pathologist and clinician. In the New York State Laboratory, with which Dr. Park is connected, the disease is studied by the pathologist, biologist, chemist, histologist and clinician, all working in close association. As to causation, the doctor was of the opinion that cancer was due to an extrinsic cause, i. e., to be parasitic in its nature. He took the analogy of vegetable life to sustain the parasitic theory, stating that the woody masses or xylomata or knots in trees suggest the tumor or cancer idea, which destroy the tree; they are frequently spoken of as tree-cancers. Tumors are also common in the lower animal forms. He believed that tumors in man and animal are due to the same general causes, and said that it was not too strong a statement to make that Dr. Gaylord and the Laboratory staff have absolutely produced adenocarcinoma by inoculation in a number of animals and that this can be produced in such a way as to afford unmistakable evidences of the infectivity of the disease. "**The Present Status of the Carcinoma Question,**" by **Dr. Nicholas Senn**. This, the doctor considered, is the most important research of to-day. Carcinoma results from atypical proliferation of epithelial cells. As carcinoma originates in epithelial cells its development is impossible in meso-blastic tissues. Histology does not support the parasitic theory. The progressive extension of a tumor into the adjacent tissues is proof positive of malignancy. This is by the lymphatics only. The increase of carcinoma is more imaginary than real. There is more basis to heredity than is believed by the profession at large. The age is important, although usually over forty it may be below twenty and in these cases it is almost always malignant. "**Early Diagnosis of Carcinoma—Methods,**" **Dr. Charles A. Powers**, Denver, Col. The salient features that the doctor desired to bring forth was the early recognition, thorough operative removal of the widest possible area, and a careful, systematic surveillance of the patient during the rest of his life. The laity should be instructed. The doctor reviewed the diagnostic reaction of the use of cancer-serum and auto-inoculation as an aid in the early diagnosis of cancer. "**The Pathology of Breast Carcinoma and Its Relation to Early Diagnosis and Treatment,**" **Dr. William S. Halsted** and **Dr. J. C. Bloodgood**. The doctor grouped the tumors under multiple, malignant, benign and those associated with various acini changes in the tissues of the breast. The doctor said: "In our experience of some 294 cases, the number of cases of malignant tumors which have been admitted to the hospital at such an early stage that the clinical picture was suggestive of a benign tumor, is about 9%, or about 23 cases. What it will be in the future I am not prepared to say." "**Carcinoma of the Cecum,**" **Dr. William J. Mayo**, Rochester, Minn. The doctor said that carcinoma of cecum occurs in 7% of all cancers of the intestines and is of the columnar cell variety. Colloidal changes are frequent. It is usually annular in form, but may present a well marked tumor. Glandular infection occurs in less than one half of the cases dying from that malady. Age is not so important a feature as is carcinoma of other organs. It is not infrequently in the comparatively young. This disease may be confused with chronic appendicitis, tuberculosis of cecum, fecal impaction, etc. The results of radical operations, both immediate and remote, are good and compare favorably with cancer in other situations of the body. "**Improved Method for Resecting High Rectal Carcinoma,**" **Dr. Robert F. Weir**, New York City. The doctor considered the Kraske operation unsatisfactory for the removal of high-seated cancers of the rectum, but practices Maunsell's operation. He especially covered the technic (illustrated by drawings), surgical cleanliness, the anus and its drainage, with a list of cases. "**The Treatment of Malignant Disease by Surgical Operation,**" **Dr. Fredric S. Dennis**, New York. The treatment considered included surgical, toxins, drugs, caustics, electricity, Röntgen rays. Surgical operation is successful only when it is performed early, when it is radical in character and when it is repeated indefinitely. Cases are not considered unless three years at least have elapsed since operation, and,

by some, this period is estimated as too short. The importance of education of physicians of necessity of early operations as the essential feature of cure should be borne in mind, as well as the importance of microscopical examinations of every growth as the only means to obtain accurate information for the future study of malignant disease. It is necessary to keep a careful record of every case with its subsequent history. He proposed that the increase of cancer is not explainable. The writer was of the opinion that the action of the toxins upon malignant tumors was only explainable upon the theory that such tumors are the result of some infectious micro-organism, and this view is strongly supported by the recently expressed opinion of Czerny. Surgical intervention is the only resource since all drugs have proved ineffectual.

Discussion: Dr. Bernays, St. Louis, believed that we were to face an epidemic of cancer and that it affects all classes. "Dare we hope for a curative remedy? I think not!" Many men had worked on this question, but all had failed to solve the nature of cancer. As to etiology, some, he thought, were of embryonal nature, some parasitic and others rudimentary developmental. He thought we might "hope to exercise a sort of prophylaxis as we now do in tuberculosis." Dr. Crile, Cleveland, spoke of a screw-clamp to close the arteries, and thus prevent hemorrhage, in operation for cancer of the tongue. Dr. Rodman, Philadelphia, said that there was accumulating evidence to show that carcinoma is due to parasitic origin; that until recently it was supposed that carcinoma was not found as frequently in the Indian and negroes, yet it is found in both those races as in the white, certainly carcinoma of the breast, and in the negro probably a little more than in the whites. Dr. Fritterer, Chicago, was opposed to the parasitic theory, but did not wish to discourage research along that line. He referred to the mechanical theory, the displacement of the epithelial cells in the deeper layers, and the Cohnheim theory. The doctor had, in the exhibit, a pathological specimen—cancer of the stomach—an implantation from an ulcerating carcinoma in the esophagus high up. Dr. Massey, Philadelphia, in speaking of cancer, thought that there was a separate entity, separate from the man or woman on which the disease feeds. He spoke of the use of the electric current, causing chemical disintegration of the growth at once under ether, which he had presented in Philadelphia in 1897. Dr. Dawbarn, New York, commended the joint paper by Drs. Halsted and Bloodgood, in the extirpation of tumors or lumps in the breast, whatsoever they might be. In operations for cancer of the tongue he believed death was caused by shock and that the chief cause of shock is hemorrhage. The doctor had forty personal operations in the region of the mouth and external carotid. Dr. Leavings, Milwaukee, referring to cancerous growths coming from a development of epithelial cells, embryonal or post-natal in character, drew an analogy between that and the embryology of the teeth or "enamel organ." Dr. McKenzie, Oregon, from the standpoint of the clinician, thought that in considering the origin of cancer, the point of locality had a great deal to do with it: that when it develops in any part of the human body it develops in tissues which are not normal anatomically and in organs which are not normal physiologically.

At the close of the morning session Dr. C. M. Jackson, of the University of Missouri, gave an interesting talk on the subject of "A Method for the Study of Relational Anatomy," in which he said that the relative inefficiency of the present courses of instructions in anatomy is largely due to the lack of a practical method of studying the topographical relations of the various organs. For this purpose sections are necessary. Method of frozen sections unsatisfactory. The author has obtained excellent results by sectioning bodies hardened by arterial injections of formalin. A detailed account of this method as applied in teaching relational anatomy in the University of Missouri, a new apparatus for making rapid and accurate drawings of sections. The possibilities of this method for teaching anatomy and surgery, and also for the study of relational anatomy by the practitioner.

Officers for following year: Dr. De Forest Willard (Philadelphia), Chairman. Dr. Jas. B. Bullitt (Louisville), Secretary.

THIRD DAY, JUNE 10th, 1901

Paper by Dr. John A. Wyeth, New York City: "Hemostasis in Amputation at the Hip-joint—A Resume of 262

Cases by the Author's Method." The operation has had 11 years trial; the author has collected 267 cases, in which the operation had been done. The operation was first made public at a meeting of the American Medical Association at Nashville in 1890. The 267 cases are classified as to neoplasms, sarcoma, epithelioma and osteo-carcinoma. While the mortality is large, the injuries were of a very severe type. The death rate in 1881 for all causes was 64%, now 19.8%. The death rate 20 years ago for all causes was equal to that for crushes from railway trucks or heavy machinery at this date. Antisepsis must share with the improved hemostasis the credit of this diminished rate of mortality. In the discussion, Dr. Means of Columbus, stated that his experience was limited to two cases. He thought that the use of these pins in hemostasis could be extended quite as well to various other portions of the body. He felt that the profession should congratulate Dr. Wyeth for the principle involved in this method of controlling hemorrhage. Dr. Henry concurred in the expressions of the value of this method of Dr. Wyeth. Dr. Walker said that the ease with which hemorrhage could be controlled was a revelation to him. He asked why the operation could not be done without the use of the pins—why not do the ligation primarily? Dr. Sylvester considered it a very scientific and satisfactory operation. He was in the habit of tying the silk-worm sutures in bow knots, and the bow knots can be untied without the use of an anaesthetic. Dr. Wright, of Bridgeport, Conn., uses a heavy rubber bandage and converts it into a roll, passing it around the groin. He has been able to produce a hemostasis which was quite satisfactory. It occluded the vessels and saved the necessity of the pins. "Autoplastic Suture in Hernia and other Ventral Wounds," Dr. L. L. McArthur, Chicago. As to Suture material, the Doctor said that he would not have presented the paper if he did not believe that it possesses additional merits, viz.: (1) The obtaining of a living suture; (2) Lessened chance of failure through avoidance of introduction of dead or foreign tissue; (3) The incorporation in the resisting cicatrix of organized white fibrous tissue. He felt that failure of cure in hernial operations by any of the recognized methods is practically due to associated infection, for the Bassini, the Andrews or the Girard, un-associated with infection can be said to be practically always successful. Dr. Powers of Denver believed that Dr. McArthur's proposition was well worthy of trial. He did not know whether the essayist had operated on any children by this method. The discussor had operated on a boy of ten years. Dr. G. F. Shimonek of Milwaukee believed that this tissue so united, was of rather low vitality, as all tissues of that kind are, and that by passing it through the opening and putting it on a stretch it must become de-vitalized. The Chair remarked that an important point to observe was that after it was sewed there was no tension. That instead of being constricted the way the tissues are when they are tied with catgut, no constriction occurs. Dr. McArthur said that he had found that the edge did not tear out any more than it would in using any other suture material. The Doctor reported a case of rather a rare type of hernia, which is spoken of as the "sacless hernia." "New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery," Drs. L. E. Schmidt and G. Kolischer (Chicago). Skiagraphy for medical purposes was especially advanced and perfected in America. Calculous deposits were especially attractive for X-Ray diagnosis. The authors' paper was elucidated by illustration, one showing a kidney and renal stone. By their method they are able to determine the course of the ureters, location on the renal pelvis, diagnosis of dilatation of the renal pelvis, and the location of the renal calculi; also the possibility of differentiating gall stones from renal stones. "Prostatotomy versus Prostatectomy for Prostatic Hypertrophy," Dr. Raymon Guiteras, New York City. The Doctor outlined the history of prostatectomy and prostatotomy, saying that each had been developed by a gradual evolution. His personal preference is the vesico-rectal method and the most important part of his technique is the inserting of two fingers high up in the rectum. It is too grave a condition, such as hypertrophy of the prostate, to allow of logrolling. There are three main classes of these cases: the first, the physiology young, suitable for radical operations; the second, older, can withstand palliative bottini. The third class fortunately small, and growing smaller are able to stand no operation whatever.

Statistics show the mortality of prostatectomy as yet to be three times that of prostatotomy.

"Prostatectomy, the Method of Choice in the Management of Prostatic Obstruction," Dr. Eugene Fuller, New York City. The Doctor opened his paper with a plea for radical operative relief in these cases. At the present time, if practitioners allow a patient to die from appendicitis without resorting to surgery or, at least to raising of surgical interference, the community at large blames him severely; the same ought to apply to prostatic obstructions. The Doctor showed how, under proper surgical management, the mortality, under favorable circumstances, is not over from 8 to 10%. The question of castration for relief of this condition is passed over and cast aside as a discarded method. The Bottini method was freely considered. "A Further Report on Permanent Catheterization," Dr. J. R. Eastman, Indianapolis, Ind. Permanent catheterization in the male was practiced in 15 cases in each case the catheter was retained for 10 days; in two cases 60 days. Cystitis was not produced in the author's cases sufficiently severe to produce symptoms. Hydrogen peroxide was introduced into the bladder. Regular flushing of the bladder was not done except in two cases. It is essential that the catheter be introduced just far enough, that the tip project into the bladder and be accurately secured. "Fallacies in the Treatment of Urethral Diseases," Dr. Robert Holmes Greene, New York City. The Doctor covered the technique pathology quite extensively and added to the realism of his subject by well-defined drawings of cases. "Perineal Prostatectomy," Dr. Parker Syms, New York City. The Doctor said that while prostatectomy by most methods had shown a large death rate, he had so far been fortunate enough in not having lost a patient and having a complete cure in all cases except the second one.

Discussion: Dr. Robert H. W. Dearborn presented the subject of an apparatus of his own for supra-pubic drainage, which had already had the test of ten years. He thoroughly described the technique thereof by specimen presented. It consists of a fountain syringe, regulated by either an artery-forceps or, as the Doctor used, the catch that comes with the syringe. Dr. Rockey considered that the question of prostatic hypertrophy was one of vastly greater importance than it seemed to receive from the profession. He believed the operation of prostatectomy has been an evolution, and that the question to decide was the method. He believed that the information was to allow the operation to become one of last resort, that it should be taken up much earlier. Dr. McGowan, of Los Angeles, had operated on about fifty old men by prostatectomy and prostatectomy; the men varied from 65 to 81 years; the results were not perfect by either method. Dr. Guiteras, speaking of retention of urine, said that the bladder ought never to be emptied at one time; never draw more than a pint the first time. In speaking of the Bottini operation, the Doctor said that it held the same position to-day as did Hysterectomy a few years ago, but that some day a good operation that could be done with ease and without danger to the patient would be devised. Other discussers were Drs. Eastman, Greene, and Syms.

Paper by Dr. J. D. Murphy, Chicago, "Pneumectomy and Pneumotomy." The doctor said that pneumectomy is frequently indicated. It can be performed with safety to the patient; the danger of pneumothorax is not great, and their unpleasant manifestations are entirely overcome when the causes of the symptoms are understood. Portions of the lung may be amputated without danger of hemorrhage and without danger of pneumothorax from division of the branches of the bronchi. Pneumotomy is frequently indicated, is not a dangerous procedure and may be accomplished with or without adhesions of the lung; the hemorrhage is usually controlled. The doctor showed why the scalpel should be used in place of the Paquelin cautery in opening pulmonary abscesses, interlobar abscesses and bronchiectatic cavities, and portrayed the probabilities of pneumectomy and pneumotomy. Dr. DeForest Willard, Philadelphia, "Removal of Foreign Bodies from the Trachea and Bronchi." Foreign bodies, the doctor said, such as seeds, nuts, toys, food, etc., are exceedingly liable, especially in children, to be sucked into the trachea during laughing, crying, etc. The violent efforts at coughing usually dislodge the offender if it has not

reached the larynx but it may be arrested at the vocal cords, or may pass on and become impacted in one of the bronchi, usually the right, from anatomical reasons. A low tracheotomy should at once be performed and a large opening made. When the object to be sought for is metallic, an X-ray representation may prove of great value. Should gangrene of the lung occur, a free incision should be made down to the pleura. "Treatment of Empyema," Dr. James H. Dunn, Minneapolis. The doctor said that the average treatment of empyema is still far from satisfactory and decidedly behind the present state of surgical science. He assigned as some of the causes of failure, tardy diagnosis, inefficient drainage and slovenly after-treatment. A pleural suppuration should be at once removed. The drainage opening should be large. The doctor, in a very interesting way, covered the technique diagnostic and prognostic features.

Dr. Vernays said that he believed that the time had come when surgery would attack the ravages of tuberculosis in the lungs and that it would be done successfully. The doctor then related postmortem findings of tuberculous tissue, which proved of great interest to the Section. The doctor believed that this department of surgery is in its infancy. Dr. Willard had so completely covered the subject of foreign bodies in the air passages that he had nothing to add. As to Dr. Dunn's paper, he said that the treatment of empyema depends on the microscopic findings in the fluid that has been drawn out by the exploratory needle. Dr. Barbet had expected to present a paper on thoracic surgery. He had performed experiments on dogs and had devised a special apparatus. Dr. Jopson, of Iowa, considered that the removal of foreign bodies from the air passages forms an important part in general surgery; that in every instance of foreign bodies in the air passages, the trachea should be opened. He did not believe that emetics, holding the patient upside down, were availing. He said that when the trachea is once opened we immediately know whether it is distal to the opening or proximal, whether it is toward the lung or whether it is located in the larynx by the breathing, and the thing in the larynx can easily be removed by a pair of forceps.

Dr. Frank, of Chicago, said that he had had experience in lung surgery in two cases and that he found from these two cases and from experiments on dogs that surgery of the lung is not as easy as most speakers would lead one to believe. The first case was that of a politician, who made a good recovery. The doctor had inserted a syringe with a catheter into the trachea and made suction. Dr. LeMoyné Wills, of Los Angeles, said that the trouble in Southern California and all parts of the country is that much opposition to anything in the way of draining the superficial cavity, or anything in the chest, that it is put off until it is too late to do any good, and that it is for the profession to overcome that opposition and not let their patients go on in a septic dying condition and then send them away to Arizona and New Mexico and Southern California, thereby putting the responsibility on the other fellow's shoulders. Dr. Norred, Minnesota, related a case of a child two and a half years of age, who in 1869, had swallowed a peanut kernel, which was drawn into the bifurcation. His two consultants said there was no hope, but he persisted and suggested that they relax the child completely and thus prevent any muscular contraction. The child was, therefore, given morphia and vomiting was provoked, whereupon the peanut kernel was dislodged and came up. And accompanying pneumonia was also checked. "And," said the doctor, "I have to say with great gratification, that the young man recovered and is in your presence this afternoon." (Applause). Dr. Keen, of Philadelphia, spoke in relation to puncturing the lungs. The points which he emphasized was the means of obtaining adhesions where none exist in puncturing the lung, and the safety of a very large suture of lung tissue to the chest wall. In the first case the doctor made his incision parallel to the ribs for about two inches, carefully dissecting the muscles, separating them as he went down, until he reached the pleura which was very easily recognized and the muscles very easily separated from the pleura. The other was the case of a woman who had a sarcoma of the chest-wall, reaching from the outer border of the breast nearly all the way back to the vertebral column. Dr. Means, of Columbus, had, within the last 18 months two cases, one of them demonstrating the possibility of recovery, after a fearful gunshot wound of the chest; in the other he was unable to reach a pus cavity. Dr. Willard, of Philadelphia, said that

satisfaction at the success of the meeting, not only from the interest manifest, but by the high-class papers presented and scientific nature of the discussions.

Adjourned.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

FIRST DAY, JUNE 4th, 1901.

The Chairman, Henry P. Newman of Chicago, presented his address in which he made some suggestions on the improvements of the methods of conducting the section meetings, and then proceeded to review the year's progress in gynecology and obstetrics. Among the most noteworthy innovations of the year is the clinical adoption of the method best known as cocaineization by spinal puncture. Bier, of Germany, made the first injection, and Tuffier, of France, followed him. The latter has now covered in his experience 400 cases and has collected the records of 2000 cases with but 6 deaths. He considers the method as absolutely safe, but in this he is opposed by others. Newman claims that its limitations are somewhat reduced, and that the method will probably never be so popular here as abroad. The patient plays a very important part in the method, which is not applicable to children and sensitive adults, nor for grave major operations. Full consciousness is not desirable. In obstetric operations the method has been found undesirable. There is no relaxation of the muscular tissue as with the use of other anesthetics. The Protozoan of Cancer. Gaylord's experiments seem to show that these micro-organisms are the cause of cancer. Until a specific be discovered, however, wherewith to destroy the disease, surgical operation will not be contraindicated, even up to the eleventh hour. The early correction of all epithelial lesions of the genital tract will largely prevent the subsequent development of malignant diseases, which is now so rapidly growing in frequency. Ovarian grafting or transplantation has gained ground during the year, as evidenced by the encouraging reports from the various experimentors. Cesarean Section for placenta previa is valuable if done under aseptic precautions and before the patient is exhausted. The operation is probably contraindicated in eclampsia. A large percentage of the gastric symptoms of pelvic disease is due to the accompanying visceral displacement, as is also a large percentage of the neurasthenia. The different splanchnoptoses, such as floating kidney, floating spleen, etc., also give rise to grave nervous manifestations. Uterine fibroids. The use of saline infusions in the treatment of the hemorrhage from these growths has grown during the year. We have now outgrown the dangerous theory that because these tumors may atrophy at the time of the menopause it is safe to leave them undisturbed until that time. The importance of prophylaxis in gynecologic treatment was emphasized. The trained nurse should supplant the monthly nurse. There will always be the need of intelligent obstetrics, while nothing but gynecology will eliminate gynecology. Dr. A. H. Cordier, of Kansas City, Mo., read a paper on Post-operative Intra-peritoneal Hemorrhage. He remarked that no condition is more horrifying than hemorrhage after an abdominal operation. The use of unstable ligature material has cost many patients their lives. His three cases of post-operative hemorrhage have occurred in easy cases. The symptoms of concealed hemorrhage very closely simulate those of shock, hence there is a danger of making a fatal mistake. In making the diagnosis he suggests the advisability of cutting one of the abdominal sutures and introducing a sterilized tube or a pair of hemostats; if hemorrhage be present the blood will begin to flow out. Many so-called cases of shock are in reality cases of post-operative hemorrhage. In such cases the only duty of the surgeon is to control the hemorrhage, not by strychnin and hot applications, but by resection. The proper use of the decinormal saline solution is of great value. It is best to introduce the fluid in two sittings, for a large quantity is needed. Dr. McMurtry, of Louisville, remarked that post-operative hemorrhage is due to breaking or slipping of a ligature, and almost invariably to the latter. He does not think that the material used has much to do with the accident. It is rather due to the method of application. Intravenous injections of salt solution should never be given while the hemorrhage is going on. Profound collapse or death may follow the loss of a very little blood

after an operation: hence the hemostats must be prompt, and in some cases packing with gauze is necessary. Dr. Gordon, of Maine, criticized Dr. Cordier's paper in two ways. First, in the material used. He has used no ligature material but catgut for 17 years, and thinks only absorbable ligatures should be used. He prefers ligating by a needle only, and always secures the first ligature by a second placed below it. He would not introduce a drainage tube in cases which do not need such a tube. Kelly, of Baltimore, reported a case of hemorrhage resulting from the early absorption of a ligature. He does not care for any other substance than silk (and fine silk) for ligatures. He always gives a good pedicle beyond the tie. Most important is a thorough review of the field after the operation. In suspected cases of hemorrhage he opens up at once, and the salt solution is given as the patient goes upon the table. Marcy, of Boston, believes that defective technique is the most common fault in hemorrhage. He favors the absorbable sutures, and thinks that the buried animal suture is the best contribution to surgery. Rubber gloves and silk will not prevent infection and irritation. Frederick, of Buffalo, has used catgut exclusively for 10 years, covering nearly 1000 cases. Formalin catgut will remain 2 to 3 weeks when tied taut. He applies first one knot and then a double knot, leaving the ends from $\frac{1}{2}$ to $\frac{3}{4}$ inch long. Dr. J. G. Clark, of Philadelphia presented a paper on the Contributing Factors in the Production of Peritonitis. He stated that in 1896 he suggested the natural method of drainage of the peritoneal cavity. He found that the peritoneal lymph currents sweep toward the diaphragm, and that the rapidity of absorption is so great as to render impossible the localization by mechanical means of infectious matter in any part of the abdominal cavity. He was astonished by the remarkable absorbing power of the peritoneum, not only for liquids, but also for solid granules. Within eight minutes after the introduction of granules into the abdominal cavity they appear about the diaphragm. After the introduction of septic organisms in the peritoneal cavity there occurs primarily a distribution. Later the leukocytes begin to disappear, and when found they contain the granules. This proves that the leukocytes are the phagocytes, killing the parasites and carrying them into the general circulation. Given a minimum amount of infection at the end of an operation, it is proper to wash out the cavity and introduce a substance which will favor absorption of the poisons. The central tendon of the diaphragm absorbs quickly, and some of the poison is eliminated through the lungs, liver, intestines, spleen and kidneys. There is no possibility of limiting the infectious material to any portion of the peritoneal cavity. Thorough irrigation followed by the leaving of one liter of 6/10% salt solution is the best method of treating patients feared to be septic. Peritoneal infusions may, however, be dangerous in ascitic cases in which the natural peritoneal drainage is already deficient, and also in cases of general surgical peritonitis. Wiggins, of New York, has found that his section cases do better after using irrigation, and have less adhesions. Kelly, of Baltimore, remarked that the whole status of drainage is changed. Formerly 95% of the cases were drained, now scarcely any. General septic peritonitis from appendicitis must be drained. He occasionally uses gauze in the abdominal cavity to sequester, not to drain. Baldy, of Philadelphia, states that Baer, of Philadelphia, long before Johns Hopkins Hospital took up the subject, closed the abdomen in desperate cases without drainage. He does not drain in 2% of his cases, and he never leaves fluid in the abdominal cavity, nor does he have much sepsis. He does not believe the fluid does the work. If the pus be streptococcal the patient will die notwithstanding irrigation. Kollischer, of Chicago, stated that no man could say in what direction the peritoneal lymph channels drain. Moreover, the poison does not remain on the surface, but penetrates the serous coat and is carried by the subserous lymph-chains. Irrigations, therefore, can only affect the surface poison and not that which has penetrated. Deaver, of Philadelphia, objects to the doing away of abdominal drainage. If we fill the infected abdominal cavity with a saline solution we leave the last stage of our patient worse than the first. He advocates practice versus theory. By invitation, Dr. M. D. Mann, of Buffalo, N. Y., read a paper entitled A New Operation for Extirpation of Cancer of the Rectum in which he stated that Edeholds has recently suggested resection of the rectum from above. The operation Mann advocates is as

follows: The rectum and vagina are well cleansed, and after exposing the bowel, the rectum is clamped above the growth and cut off; the meso-rectum and rectum are then cut away and all large vessels tied. The lower end of the rectum is then seized and drawn up; a Murphy button is inserted and the two ends clamped, the lower button being held up by 1 or 2 fingers introduced into the rectum.

SECOND DAY, JUNE 5th, 1901.

Dr. O. Thienhaus, of Milwaukee, Wis., read a paper entitled *Atresia hymenalis*, and presented a specimen of a girl 14 years of age, the condition resulting from atresia of the hymen. Infection of the vulva and vagina and inflammation of these structures, he claims, is the main cause of atresia.

Traumatism, pessaries and burnings may also cause the condition. An examination should be made in all cases of delayed menstruation. Hematokolpos is discovered and a hematosalpinx suspected and abdominal incision should first be made, and the tubal tumor be removed and then the incision made below. Goldspohn, of Chicago, would avoid opening the abdomen when the accumulation existed in the vagina only as it usually did. Dr. A. Goldspohn, of Chicago, presented a paper on *The Indications, Technique and Results of Salpingostomy with Ignipuncture of the Ovaries*. He remarked that ovarian disease is due largely to inflammatory action. Conservative work on the ovaries was commenced by Karl Schroeder, who was soon followed by A. Martin, Polk, Dudley and others. Personally he has been able to follow 97 cases after conservative processes had been adopted. An examination of 27 of these showed the parts in perfect health. Cases without pus, extreme adhesions or retroversion of the uterus may be operated upon through the vagina. Nine of such cases he had followed and 5 are well; the other 4 are ailing. In the larger number of cases a decided retroversion or retroversion existed with adhesions, but no pus. Such cases were operated upon through the vaginal canal, and when so treated they stand the test of pregnancy and do not permit of the return of the abdominal condition. He has followed 56 cases of this class, and 49 or 87.5% show perfect results, 9% give partial results, and only 3% showed positive failures. In patients who are not near the menopause and who are not tainted by tuberculosis or malignant disease, a part of one or both ovaries should be retained. Also in extirpating dermoids of the ovary, a part of the organ should be retained if possible. Asepsis of the highest degree is necessary in the removal of the adnexa, and the smallest amount of suture material possible should be used, as should also sterile rubber gloves. A generous medium ventral incision is best for the conservative treatment in those cases in which extreme adhesions and pus are found. In less severe cases the inguinal ring is better. The vaginal operation does not provide an easy access for excision of the ovaries. Ignipuncture is valuable in many cases. The writer then presented the histories of typical cases. Bovee of Washington claimed that much can be done by the conservative surgery of the ovaries, and less in diseased condition of the tubes. The object of conservative surgery is primarily the health of the individual, secondarily function, and thirdly mental impression. Many cases of simple punctures will result in dense adhesions. Sclerocystic ovaries are not suitable for resection, but should be removed. Eastman, of Indianapolis, remarked that the retention of a stormy menstruation is better than the abolition of menstruation, and also the retention of the sexual impulse.

Goldspohn, in closing the discussion, said that in his 97 cases there followed 10 pregnancies. Ventral suspension by the sound ligaments is next in value to the inguinal operation, but it is not ideal.

Dr. A. J. Downes, of Philadelphia, presented a paper on *Electrothermic Hemostasis in Abdominal and Pelvic Surgery*.

Dr. Downes defined Ideal Hemostasis as that method by which not only the vessels are occluded with certainty but so that no complication, either immediate or remote, results. He pointed out how no correct method fulfilled the definition. Reference was made to Keith's original application of pressure and heat to blood vessels and to Skene's development of the first electro forceps. Dr. Downes exhibited new instruments, electro thermic angiostribe forceps, electro thermic forceps, and artery forceps electro-therm. They are rapid and certain in use

and free from the objection to earlier instruments. The essential requirements in electro thermic hemostasis were pointed out, as also the safeguards. A number of abdominal operations in which the hemostasis was used were reported, including appendectomies, hysterectomies, salpingo oophorectomies, ovarian cysts, ovarian abscesses. The necessity of a meter in the circuit and mathematical exactness was insisted upon. Aseptic nonadhering stumps were claimed as also greater freedom from pain after sections.

Martin, of Chicago, remarked that the combining of heat with a crushing instrument is a distinct advantage. Anything that will enable the surgeon to do away with the ligature is great progress. The white material formed by the electricity is a homogenous tissue without evidence of blood vessels or nerves in the compressed area.

Dr. E. E. Montgomery, of Philadelphia, opened the symposium on uterine fibroid by a paper entitled *How Shall we Deal with Uterine Myomata?* He states that much of the good apparently done by the animal extracts in the treatment of uterine neoplasms is due to suggestion. The thyroid extract has been most useful, its action being exerted upon the mucous membrane. He would not use these extracts in cases in which surgery should be used. In removing myomata the uterine incision should be longitudinal, the growth seized by tenacula and extirpated. After removal of all growths the ragged tissues should be excised and the uterine wound sutured. In extensive wounding of the uterus a gauze drain should be introduced through the abdominal wall. The number of growths is not so important as the size of the tumors. Small fibroids that do not give rise to symptoms need not be removed. Small fibroids producing hemorrhage are usually submucous and should then be removed through the vagina.

Small multiple fibroids inaccessible to the vagina should be removed from above. Eshman, of Indianapolis, stated that he did not find to-day the large fibroids seen 10-15 years ago. He regards the menopause as a dangerous period when degenerative changes are liable to occur in these uterine tumors. When one fibroid is present no one can say there are not others. Conservatism means the conservation of the woman's health, and this is best done by hysterectomy. Nahten, of Louisville, does not believe every fibroid tumor should be removed. But only when they give rise to symptoms. He does not believe in oophorectomy, nor in myomectomy. He would only do a hysterectomy and also take out the cervix in order to avoid subsequent cancer. He gets the best results per vaginam, if the tumor be not too large. He removes the uterus first after clamping, and then ligates the vessel. Dudley, of New York, would do a myomectomy provided the appendages are healthy and the uterus will not be so scarred as to give rise to trouble. Dr. J. M. Baldy, of Philadelphia, read a paper entitled *Cancer of the Uterine Neck*, in which he remarked that this disease is surgery's disgrace. The best statistics show but 5% recovery. The best recorded statistics are those of Johns Hopkins Hospital, with 20% recovery, but this does not include a large number of inoperable cases, and again some of the cases reported as cured are but 9 to 14 months old, too early to warrant an absolute cure. The microscope is not a sure means of diagnosis, and therefore some cases are operated upon that are not cancerous. Winter's statistics from Germany show that the disease is almost incurable. The early discovery of the disease is most important. The question of the laboratory is becoming a fad. Clinical observations of facts precede the laboratory, and are more important. Hemorrhage is the most important early symptom. Carstus, of Detroit, and Zinke, of Cincinnati, believe that early operation is a sure cure. Clark, of Philadelphia, would not trust solely to clinical evidence. Ries, of Chicago, objected to the reader's paper. He thinks that the operation of total extirpation of the glands, broad ligament, round ligament, and all other tissues will cure the patient. Recurrence occurs in a large majority of cases within six months. Wertheim's primary mortality is large, but of the cases that have recovered no recurrence has taken place. The mortality of this extensive operation is 10%. Kollischer, of Chicago, claimed that Baldy's statistics are absolutely correct. Cancer of the portio, however, is relatively harmless since it can be cured. Baldy, in closing, stated that recurrence when it does take place does so in the wound and below, not above, hence

the extirpation of the glands is uncalled for. No man can remove every gland from the pelvis of a living woman. Dr. J. Wesley Bovee, of Washington, D. C., presented a paper on **The Relative Merits of the Different Methods of Utero-Ureteral Anastomosis**, and describes some of his experimental work in this line of surgery. He describes the four methods, namely end to end, side to side, end to side, and obliquely end to end. The indications are not the same for each method.

Most of the reported cases of ureteral injury requiring this operation have resulted accidentally in uterine operations.

Dr. A. Plamer Dudley, of New York, read a paper on **Some Results of Ovarian Surgery with Further Report upon Intra-uterine Inflammation of Ovarian Tissues**. He has done 190 such operations to date without a failure, six cases of intra-uterine inflammation of the ovary being included. In almost all the cases some other work was performed in addition to the work on the ovary. He cannot believe that because a woman's ovaries are gone she should also lose her womb. The age of the patient and her social position, her previous history, the patient's wishes, and the diseased condition of the ovaries found will all influence the operation. Only young women are open to the operation. The hard working woman is not a suitable case. The history of a hereditary taint of syphilis, tuberculosis, or other disease, would debar the operation. Uterine gonorrheal infections and fibroid conditions greatly distorting the uterus would prevent conservative work. One hundred and thirty-seven cases of the 190 are cured, and only 42 have not been heard from. Twenty-eight pregnancies have followed the operation. He uses a fine floss silk which cannot be bought at an instrument store. He does not use catgut, nor does he employ the thermo or galvanocautery. He has had no case of ovarian suppuration. The dangers of ovarian transplantation are three-fold; the implantation of diseased tissue; the development of ovarian cystomata from this tissue; and the development of an abdominal pregnancy. He modifies the technique as follows: He implants the ovarian structure attacked to its own ligaments into the horn of the uterus and stitches the graft so that the ovarian tissue is dependent inside the uterus. Goldspohn, of Chicago, would never use any suture material upon the ovary that is not absorbable. Golfe, of New York, prefers doing his conservative work on the ovaries and tubes through the vaginal vault.

Dr. Howard A. Kelly, of Baltimore, presented a magic lantern exhibition of **The Various Incisions Appropriate to the Different Renal Operations**. He showed the best incision for suspension of the kidney, and that when the kidney is enlarged and its enucleation liable to be attended with difficulty. Also the method of removing the kidney with its ureter. The author's plan of nephro-ureterectomy without division of muscular fibers avoids the extensive wound and the weakening of the abdominal wall following the long incision from the back down to the symphysis pubis. He makes two incisions instead.

THIRD DAY, JUNE 6th, 1901.

Dr. Emil Ries, of Chicago, read a paper on **A New Operation for Retrodisplacement of the Uterus**. He remarked that shortening of the round ligament met with considerable favor in this country and abroad. Shortening of the utero-sacral ligament was not received with favor. The vaginal operation which he now does will preserve the mobility of the uterus and will not depend on serous adhesions nor interfere with the function of the tube. January 13, 1899, he operated on his first case. Since then he has operated 20 times. The patient is placed in the lithotomy position, the anterior lip of the cervix is seized with vulsellum forceps, and an incision made in front of the cervix extending up to the uterus. The vault is then opened posteriorly, the fundus of the uterus is drawn down into the vagina, and the appendages are operated upon, and whatever is left is returned. After this vaginal celeotomy is performed, his special operation is done. The round ligament is detached for 4 to 5 cm., and a long catgut suture passed through the ligament and then around the ligament. The thread is left long, and the needle remains attached. The same is done on the other side. An incision or tunnel is now made across the uterus from one to the other round ligament, midway between the mucous and serous surfaces. After this tunnel is formed a curved artery forcep is passed through, grasps the needle and

thread on that side and pulls them through to the opposite side. The same is done with the other thread. Thus far no traction has been made upon the ligaments. The thread only passed through the tunnel on the anterior surface of the uterus. The fundus is now pushed back into the peritoneal cavity and the threads are pulled upon, whereupon the ligaments pass through the tunnel. They are thus shortened the length of the tunnel or more. They pass through a raw surface so that adhesions form quickly and the ligaments are held in their new position. The peritoneum of the bladder is stitched to the peritoneum of the uterus by catgut and a vaginal wound is then sutured. The after treatment is the same as after an ordinary vaginal celeotomy. There were 14 operations in 1899 to 1900. In all examined (7) the uterus remained in good condition. In one case pregnancy followed and the uterus did not fall posteriorly. Dr. Franklin H. Martin, of Chicago, read on the **Surgical Treatment of Retroversion of the Uterus**. He gave a short historical sketch of Alexander's operation. The troubles arising from suture material have been the cause of the numerous modifications of the Alexander operation. He then described his operation for this condition which, he claims, is superior to all others because it insures a uniform shortening and firm fixation of the ligaments without ligatures, and hence without the formation of fistulous tracts. It seldom causes pain at the traction. He has performed 61 cases up to September 29, 1900, with 7 cases of pregnancy, 6 of which passed through a normal labor, and one aborted without apparent cause. Martin then gave a historical sketch of the operation of ventral suspension which he states was first practiced by Olshausen and then by Kelly. If the suspension is accompanied by an absorbable suture the operation will often fail. Fowler's suggestion of suspending the uterus from the urachus was a distinct advance. Martin prefers to use a strip of peritoneal tissue which is not so firm as the urachus, also, the urachus may be absent or in some cases it remains pervious from the bladder-end. He has done 173 operations by his method of suspension by peritoneal strip. No permanent buried sutures are required. The abdomen is opened in the Trendelenburg position, the uterus is freed and also the posterior surface of the broad ligament. The uterus is then brought forward and a strip of peritoneum is dissected free from the abdominal wall one-half inch wide and three inches in length. A needle is passed through the uterus at the fundus from behind forward. The strip of peritoneum is grasped and drawn through and the free end sutured by small catgut sutures to the peritoneal surface of the abdominal wound above the uterus. The uterus is also temporarily held forward by small catgut sutures. In 173 cases there have been 9 failures including six deaths. Goffe, of New York, remarked that a misconception of the dynamics of the female pelvis is the cause of much of the wrong treatment of retrodisplacement. The symphysis pubis is on a lower level than the tip of the coccyx in the normal condition. The uterus lies on its anterior face and is held in place by its ligaments. The perineum is not a support.

The most important ligamentous support are the utero-sacral ligaments plus the utero-vesical ligaments. The ideal operation for the restoration of the uterus to its normal position is by means of the utero-sacral ligaments. If these cannot be used the round ligaments are next best, and then ventral suspension. He is opposed to the operation which involves opening of the abdominal wall for the cure of retroversion. He denounces Alexander's operation in toto. Gordon, of Maine, protested against this so-called conservative surgery. After removal of the appendages the uterus is a gestation-bag without subsequent use. He would therefore remove the uterus in these cases. Goldspohn, of Chicago, claimed that the round ligaments are the only structures that can be rationally used for the cure of this condition, because they are part of the uterus. The uterus has "arms," and these arms should be used. The round ligaments are wedge shaped, longer near the uterus than at the abdominal wall. When the round ligaments are folded upon themselves the thick part is used and the weak part left. Alexander's operation is better because it does away with the weak position of the ligament. Kelly, of Baltimore, claimed that the ventral suspension was more rational than the operation of shortening the round ligaments. These ligaments, in the normal condition, are always flaccid structures with a kink in them. He has performed 214 ventral suspensions. 43 of the patients became pregnant with-

out trouble following. In most cases the uterus remained in good position. A symposium on Obstetrics was opened by Dr. Joseph Price, of Philadelphia, whose paper was entitled *Obstetrics as a Specialty*. Dr. E. Gustave Zinke, of Cincinnati, followed with a paper on *The Practice of Obstetrics as it is and as it should be*, in which he dwelt on the value of antiseptics and asepsis, the differences experienced in the management of labor at the home of patients versus the management of labor in lying-in hospitals. The inadequacy of obstetrics fees was then considered and the very important question as to whether or not the training and practice of midwives should be encouraged. Dr. J. F. Moran, of Washington, D. C., in his paper on *The Prophylaxis and Treatment of Puerperal Sepsis*, made a bacteriologic and pathologic study of puerperal sepsis and the normal and pathologic vaginal secretions before and after labor. He reviewed the question of the treatment of puerperal sepsis including the unsatisfactory results obtained from the antitonic serums. Dr. H. D. Fry, of Washington, D. C., presented a paper on *The Indications and Contraindications for the Use of the Curette in Obstetric Practice*, in which he emphasized the great harm that results from the too indiscriminate use of the curette. He believes that as a rule there is too much interference with the uterus in puerperal fever. The curette should not be used until the indications are marked, as a putrid discharge from the uterine cavity, with an escape of a grumous material. Dr. W. D. Porter, of Cincinnati, in his paper on *Position of the Patient during Delivery*, claimed that the usual obstetric position was an unfortunate and even bad position for the patient to occupy. He favors placing the patient across the bed on a Kelly pad, with the hips projecting well over the edge of the bed. This increases the size of the conjugate and renders the patient easy of access for whatever obstetric manipulation or operation that may be required. Dr. George J. Engelmann, of Boston, read a paper on *The Increasing Sterility of American Women*, on which he made the statement that the percentage of sterility in the United States is higher now than that reported in any other country, the percentage of miscarriage and divorce is likewise higher, while that of fecundity is lower than in any other country. In the one century that has passed the positions of American women as regards the reproductive function have been relegated from that of pre-eminence to one inferior to that of women of all other countries. Sterility, one hundred years ago the least, is now the greatest, and this with miscarriage, have increased as gynecological science has progressed. Twenty per cent. of miscarriages are now sterile, while a century ago only 2% were sterile. The fecundity, one hundred years ago was 6 children to a family; now it is not two children to a family. The causes are moral rather than medical. The sterility in graduates from female colleges is 33%. Greater luxury goes hand in hand with higher sterility. The European general fecundity is 45%; French Canadian 21%; the Colonial period of this country 6%; at the close of the Eighteenth century 4½%; now in this country 1.8% to 2% and for college graduates 1.4%. Miscarriage occurs once to 5½ labors at full term according to the books.

In Europe it occurs once to 3.3 labors and in this country once to 2.8 labors. Duff, of Pittsburg, considers this a most important subject. He remarked that civilization and Christianity increases sterility. We are past becoming a nation of abstinence, and herein lies the trouble. Dr. W. H. Nathan, of Louisville, read a paper on *ectopic gestation*, and presented some specimens, one of which he believed to be ovarian in nature. As regards the treatment of this accident before rupture he thinks that vaginal method is preferable; also after rupture when the blood is confined between the broad ligament layer or in the pouch of Douglas; and in intraabdominal rupture when there is but little hemorrhage. In all other conditions the suprapubic method should be

SECTION ON OPHTHALMOLOGY.

FIRST DAY, JUNE 4th, 1901.

The meeting was called to order at 2 P. M. by the Chairman of the Section, Dr. J. A. Lippincott, of Pittsburg, Pa. His address embraced a historical retrospect of ophthalmology and the achievements of Von Graefe, Donders, Helmholtz, and others. He called attention to the problems still to be solved in the treatment of the extrinsic ocular muscle, heterophoria, and strabismus; also the changes produced by toxic agents. He referred in his address to the fiftieth anniversary of the invention of the ophthalmoscope and the fifty years of ever-increasing usefulness in ophthalmology that followed its introduction into ophthalmic practice.

"Treatment of Strabismus; Measures Other than Operative." By Dr. Edward Jackson, Denver Col. The author states that the operative treatment of strabismus is less applicable than non-operative measures. In order to bring about a perfect cure, some non-operative treatment is requisite. The objects in view are: 1. To bring about normal innervation of the muscles concerned in the movements of the eyeball, by removing abnormal requirements; 2. To keep the eyes as far as is possible upon the best plane of visual acuity, and to equalize the efforts that are required of them; 3. To eradicate abnormal ways of using the eyes, especially when one eye is used, to the practical non-use of its fellow; 4. To develop normal binocular vision. In the majority of cases, treatment should be instituted as soon as the strabismus is first noticed. The establishment and perfection of binocular vision is the aim of the non-operative treatment, and from a practical point of view, the correction of refractive errors, stands pre-eminent in the treatment of strabismus. The occlusion bandage, constantly and correctly applied in young children, is of value. Intelligently performed skiascopy is essential. Mydriatics are of no use unless they absolutely paralyze accommodation. Of the apparatuses employed for the development of binocular vision (the primary object being to induce the patient to see with both eyes at once), Jackson prefers the fusion tubes of Priestly Smith, and especially in the form shown by him before the Section. Next to these he prefers the reflecting stereoscope as modified by Worth. Ordinary stereoscope lenses are so decentered that they practically act like prisms with bases out.

"Treatment of Strabismus; Operative Measures." Dr. C. F. Clark, of Columbus, Ohio, the author of this paper, calls attention to, and discusses the variety of, opinions that exist among ophthalmologists: 1. As to the degree of deviation and the character of the cases which they consider proper subjects for operation; 2. As to the age at which an operation should be performed; 3. As to the choice between tenotomy and advancement; 4. As to the amount of deviation that may be safely corrected by tenotomy; 5. As to whether the operation should be confined to the eye which most constantly deviates or its effect distributed between the two eyes so as to preserve ocular balance; 6. As to full correction of the error in the first operation or delaying a portion of the operative procedure until the effect of the first division may be properly established; 7. As to the practicability of partial or graduated tenotomy or advancement; 8. As to the value of orthoptic exercise before and after operation; 9. As to the value of tests made with prisms and otherwise during the progress of an operation; 10. As to the importance of the subconjunctival method of Snellen and of suturing the conjunctival wound; 11. As to the necessity of bandaging one or both eyes after an operation for tenotomy or advancement; 12. As to the relative importance of operations upon the superior and inferior recti-muscles in cases of hyperphoria and hyperopia associated with lateral deviations, and 13. As to the most approved form of operation for tenotomy and advancement. The author predicts that within a few years many of those who have heretofore depended mainly upon tenotomy for the correction of strabismus will find themselves adopting the more tedious but far more conservative operation of advancement or resection, almost as a routine practice. The peculiar insertion of the superior and inferior recti muscles should be taken into consideration. Whether tenotomy or advancement are adopted, the operative effect must be so distributed among the various ocular muscles as to preserve the control of the eyes in all ordinary movements. The well-marked heterony-

mous diplopia, with the images widely separated, which not infrequently results after carefully performed operations for convergent strabismus and dependent upon the presence of what is sometimes called a false macula, should not disconcert the surgeon, as it rarely causes serious disturbance, although it increases the difficulty in determining the result obtained from the operation. The author is convinced that in the operative correction of squint, advancement or resection combined with a very limited tenotomy ought, as a rule, be performed in place of a simple tenotomy.

"Strabismus: Its Treatment." Dr. A. E. Davis, of New York City, read this paper by invitation. After considering the different tests for strabismus, he states that it is desirable that a uniform or standard set of tests be adopted for accurately measuring strabismus. He makes a plea for a better understanding, not only of the physiological action of the ocular muscles, but of physiology in general, by those treating cases of strabismus. He believes that in most cases of convergent squint, the amblyopia is acquired and functional, and only in rare instances is it congenital. As soon as the strabismus is observed, the non-operative treatment is capable of doing considerable good. By means of this manner of treatment, if instituted in time, forced fixation and suppression of the image in the squinting eye are prevented, fusion of the images assisted, and true binocular single vision frequently preserved. About 30% of all cases of strabismus may be cured simply by the non-operative treatment. As soon as non-operative measures cease to bring improvement, operation should be undertaken; but if operation is delayed after this, it becomes not only useless, but harmful, increasing the amblyopia, because the habit of suppressing the image in the squinting eye persists. He believes that after operation the stereoscope, occlusion bandage, bar-reading, glasses, etc., are very useful. He recommends Panas' method of operating for strabismus as safe, quick and efficient; but it should never be performed while the patient's eyes are being influenced by a mydriatic.

"The Cosmetic and Visual Results in Squint." Dr. J. M. Ray, of Louisville, Ky., the author of this paper, believes that glasses should be adjusted to the eyes of children affected with strabismus as early as possible, depending upon the power of the parent to control the child. The glasses should always be worn for a long enough time to ascertain their effect upon convergence before an operation is undertaken. Dr. Ray considers the use of the exclusion pad and orthoptic exercises as advisable steps, principally for preserving the power of simultaneous action of the muscles when the child arrives at the proper age for operation. Parallelism of the visual lines does not mean single binocular vision, and the latter is not present in more than 7% of cases of strabismus. Cosmetic results can be produced and preserved when the power of fusion is absent, both in monocular squint attended by considerable amblyopia as well as in alternating squint. In the latter variety, if the hypermetropia is high, the chances for the production of parallelism are better than when the hypermetropia is low. The amount of abduction present in the corresponding externus influences the effect of a tenotomy to a considerable degree. Two tenotomies on the same internus is to be considered as bad surgery on account of the resulting sinking of the caruncle and the divergence which later ensues. From a cosmetic point of view the operative correction of strabismus is not as simple as supposed, especially when one considers the noticeable exophthalmos and the both inward and outward limitations of the ocular excursions which sometimes follow. A study of 100 cases during the past four years showed that binocular vision was rarely produced. Glasses should always be tried, but stereoscopic exercises are of little value.

Discussion: Dr. C. M. Culver, of Albany, N. Y., believed that the operation for squint was like that of talipes, in that it does not cure, but provides for a cure. In order to be fair to the patient, non-operative treatment should be instituted before the operation. Dr. F. C. Todd, of Minneapolis, Minn., believed that the length of time prevented the proper execution of the non-operative treatment, although it appears that the patients ought to be willing to take the time instead of subjecting themselves to repeated operations. He is of the opinion that the operation of advancement is steadily gaining ground, notwithstanding that tenotomy is still in vogue. Dr. G. C. Savage, of Nash-

ville, Tenn., discussed the application of the terms "convergence," "planing," and "parallelism." Dr. A. R. Baker, of Cleveland, Ohio, considers the bandage not always necessary, but often required, that alternating squint in young individuals is not so difficult as is supposed, and that it can be cured by proper glasses and exercise. Dr. F. C. Hotz, of Chicago, endorses the distribution of the operative effect among the two eyes so as to preserve the harmonious action of the muscles. He advocates simple tenotomy in mild cases, advancement in cases of medium degree, and both in excessive cases. In alternating squint of modern degree simple tenotomy will do the work perfectly well. Dr. D. M. Campbell, of Detroit, Mich., believed that the problem varies according to the variety of strabismus. A complicated strabismus, such as a convergent strabismus and a turning up of one eye, is a different problem than a simple strabismus. Many cases of convergent strabismus may be cured with a tenotomy, but a post-operative divergent strabismus cannot be treated by tenotomy of the external recti.

Dr. C. A. Veasey, Philadelphia, stated that the method employed in the service of Dr. de Schweinitz, at the Jefferson Medical Hospital, was a combination of several of the methods described with some modifications. The patient was first glassed, and it was insisted that the full correction of the refractive error should be constantly worn. The angle of squint was carefully measured from time to time to note improvement. If the angle was small orthoptic exercises with the stereoscope were employed at once. If the angle was large, operation was performed after the glasses had produced their full effect. A tenotomy, alone or combined with advancement, was employed. Convergent squints were slightly undercorrected and divergent squints slightly overcorrected and orthoptic exercises used at once. By this method the cosmetic effect was not only good, but binocular single vision was frequently obtained.

"Concerning the Check Ligament." By Dr. J. E. Colburn, of Chicago, Ill. The author presented a composite drawing, the result of many experiments on the cadaver, and demonstrating the orbito-ocular and orbito-muscular bands of the check ligament, with a discussion of the various groups of bands and the function of the check ligament.

SECOND DAY, JUNE 5th, 1901.

The morning session opened with an exhibition of specimens and new instruments, consisting of ophthalmoscopes and ophthalmic literature, as an observation of the fiftieth anniversary of the invention of the ophthalmoscope (See Western News of this issue). Dr. H. Friedenwald, of Baltimore, Md., read a paper entitled, "Address on the Origin and Development of the Instrument, together with a description of the Historic Exhibit of Ophthalmoscopes and Publications on Ophthalmoscopy Prepared for this Meeting, followed by an address on the life of Reimnitz, by Dr. Casey A. Wood.

"Iarsadenitis Meibomica," according to the definition of the author, Dr. M. F. Weymann, of St. Joseph, Mo., is as follows: "A subacute chronic infection of the Meibomian glands, tending to periodical acute exacerbation, and secondarily, altering the whole structure of the tarsal cartilages, chiefly the upper." According to Weymann chalazia may undergo suppuration and chronic inflammatory softening. It is the latter which gives rise to the condition he calls tarsadenitis Meibomica. The most pronounced symptoms are smarting and itching, the appearance of "nipple orifices" which cannot be squeezed to such an extent as to disappear, and, above all, a peculiar alligator-leather appearance of the conjunctiva lining the tarsal cartilage.

"Report of a Case of Retroflexion of the Iris." Dr. A. A. Hubbell, of Buffalo, N. Y., reports a case of retroflexion of the iris in a laborer, aged 56, who struck the left side of his head against a pavement. The eyes had previously always been healthy. The patient had sustained a violent concussion, and when he first presented himself there was ecchymosis of the left eyelid and deep congestion of the episcleral tissues, but no pain. The cornea was slightly hazy, there was hyphemia, and tension somewhat diminished notwithstanding that there had been no laceration. After treatment the blood became absorbed. Examination showed no trace of the iris, ciliary processes, or crystalline lens. The invisibility of the iris was explained as due to its being reflected against the ciliary body, and Hubbell believes that the lens was absorbed.

"Treatment of Heterophoria: Non-Surgical Measures," by Dr. George M. Gould, of Philadelphia. The author of this paper concludes from experience in his private practice that there is no surgical treatment, properly speaking, of heterophoria. He states that for six years he has observed no case of heterophoria requiring operation, and that he has obtained no unsatisfactory results when the cases were treated with common sense instead of with the scissors. He believes that in hyperphoria accurate refraction, temporary but partial prismatic neutralization, supplemented by ocular gymnastics and the observance of ophthalmic hygiene constitute the proper treatment. He strongly advocates the non-surgical treatment of exophoria as indicated by the following remarks: "If words are not minced, then tendon-cutting in exophoria is positive malpractice." "Surgery is the despair of medicine, and we should never adopt surgical methods while there is a glimmer of hope by natural means in the direction indicated by the subtle and adherent strivings for normality." The other ocular insufficiencies were also discussed by him.

"Treatment of Heterophoria: Surgical Treatment," Dr. G. C. Savage, of Nashville, Tenn., believed that no operation should be done in cases of heterophoria intrinsic in character where gymnastic exercises, even if required for a long time, would cause relief. The two objects in view in operating on eye muscles are the alteration of the muscular tension and the change of plane of action. The existence of a cyclophoria should be first excluded. In no variety of heterophoria should a complete tenotomy ever be performed. The plane of a muscle should never be altered unless a correction of cyclophoria is required. Cyclophoria may be present alone, and so high as to require operative relief which is accomplished by operating upon both superior or inferior recti muscles. He describes the various operations for sthenic and asthenic forms of heterophoria with their various complications.

Discussions: Dr. S. D. Risley, of Philadelphia, stated that the profession cannot afford to be dogmatic on this subject. He endorses the conclusion of Dr. Savage. He called attention to the direction of the orbital planes which may be altered by distortions of the skull itself. The aponeurotic pole, the check ligament, the orbital attachments, all may be modified by abnormalities of the conditions in the orbit. Dr. M. F. Weymann, of St. Joseph, Mo., believed that we cannot be entirely guided by a mathematical rule in cyclophoric conditions. Dr. D. S. Reynolds, of Louisville, Ky., called attention to the fact that general nutrition bears a definite relation to ametropia and abnormal conditions of the eyeball. Age, habit, loss of sleep, coffee, etc., must all be taken into consideration. The physical conformations, as stated by Dr. Risley, are never to be lost sight of. Even the bones of the neck, as well as extraneous causes, modify these conditions of the eye. Dr. J. E. Colburn, Chicago, Ill., believes that errors of refraction cause pseudo-heterophoria, and that in many instances general debility itself is not the cause, but it nevertheless unveils many cases of heterophoria. There is a neuromuscular condition which plays an important part; it may remain, and can only be overcome by improvement of the general condition. Dr. C. H. Williams, of Boston, Mass., before operating on the external ocular muscles, always ascertains the variety and the amount of deviation. He showed before the section an instrument devised by him for this purpose. Dr. F. Allport, of Chicago, Ill., rarely performs a tenotomy for asthenopia, and rarely prescribes prisms. Good sanitary surroundings, the correction of ametropia rarely compels one to do a tenotomy. Dr. H. Woods, of Baltimore, Md., is of the opinion that school and home hygiene has much to do with the treatment of these conditions. Although the non-operative treatment sometimes gives remarkable results, some cases which in a few months do not yield to a non-operative treatment require tenotomy. Dr. L. Connor, of Detroit, Mich., believed that the following causes should be looked for: 1, reflex causes, as in nasal disease; 2, malnutrition of some portion of the eye so that the muscles are unable to perform their functions, as is the case with muscles in any other portion of the body; 3, physiological lack of power; 4, anatomical defects. When we have definitely determined that anatomi-

cal defect is the cause, operation is the only procedure. The influence on the patient by the operator and also the effect of the operation itself frequently benefit. Dr. A. E. Davis, of New York City, stated that it is not only the muscles, but nerves that should be considered.

"Table of Paralysis of Ocular Muscles," by Dr. H. M. Starkey, of Chicago, Ill. The author of this paper presented a table reviewing the nomenclature of the associated movements of the eye, the muscles producing these movements and a delineation of the law of projection.

In the discussion, Dr. F. C. Hotz, of Chicago, called attention to the difficulty which is frequently encountered in teaching the paralyzes of the ocular muscles. Too much stress is laid on describing the paralysis of each individual muscle, instead of practically emphasizing prominent combination of symptoms. Dr. W. Wilder, of Chicago, believed that the difficulties are not in ocular paralysis, but in paresis where there is not much diplopia.

The Extraction of Hard Cataract Without Iridectomy by Dr. S. D. Risley, of Philadelphia. Until recently Risley has performed cataract extraction by the combined method, but prompted by the favorable report of other ophthalmic surgeons, has in selected cases adopted the method of simple extraction. The requisites for the selection of such a case are the absence of any special pathological history, the absence of pronounced disease of the uveal tract, an iris which reacts promptly, a pupil which is readily responsive, and dilates to at least a moderate degree under a mydriatic, and a ripe cataract. He describes the operation in detail. After the last sterilization of the eye he instills a solution of salicylate of eserine. He states that this maintains for an hour or more the contraction of the pupil and diminished the chances of prolapse during the most critical period of convalescence. After this atropine is resumed. He prefers to trust to the absorption of small remnants of cortex rather than risk rupturing the suspensory ligament by continuous efforts to remove the debris by manipulation and irrigation of the anterior chamber. He appends a table of cases showing the notes of the operation, the description of convalescence, the complications and the vision.

THIRD DAY, JUNE 6th, 1901

The first paper read was by Dr. H. V. Wuerdemann, of Milwaukee, Wis., on **Economic Limitations of the Visual Acuity in the Various Trades and Professions.** The meaning of blindness as used in daily life is a much narrower one than is embraced in the scientific term. It has been determined that ordinary coarse work like that of a common laborer does not require more than one-half of the normal for a condition of success, but on the other hand a corresponding diminution in the vision of a skilled mechanic would so decrease the clearness of the retinal impressions to which he has been accustomed in the performance of his duties, as to seriously hamper him. Individual members of certain occupations do not have the same visual demands exacted from them. Dr. Wuerdemann divides the occupation into two groups. The occupations requiring higher degrees of visual acuity and a range from 0.75 to 0.15 are, medicine, theology, law, art, engineering, students of all professions, fine mechanics, iron and steel workers, rolling mill workers, machinists and metal workers, musical instrument makers, the linen industry, the textile industry, the silk industry, paper workers, leather workers, garment makers, printers, marine employes, mine workers, railway and steamship employes (including city roads), soldiers and sailors, telegraph operators and skilled labor generally. Group 2. The trades requiring lower degrees of visual acuity and a range from 0.50 to 0.05 are, glass blowers, mineral workers, quarry men, builders, pottery makers, brick makers, workers in the chemical industries, employes in gas and water works, paper makers, wood workers, mill employes, manufacturers of food articles, sugar factory employes, brewers and maltsters, tobacco workers, chimney sweepers, street railway employes (horse cars), employes of elevators and wine cellars, teamsters, bargemen on inland waters (rivers, etc.), farmers, day laborers, unskilled labor, etc. The author compiled a table showing the scientific standard of the visual acuity converted into economic terms.

There was then a report of the railway committee of the ophthalmic section of the American Medical Association by the Chairman, Dr. Allport, of Chicago, Ill., followed

by Dr. Allport, who read a paper entitled **Further Report on the Visual and Aural Qualifications of Transportation Employees.** The author obtained statistics from numerous railroads concerning this subject and shows the statistics and answers to the question, "Do you require examination from time to time, and if so, at what intervals, or under what circumstances?" "Do you require perfect vision, color sense and hearing in new employes, and what concessions do you permit from a perfect standard in the case of old employes?" "Do you permit old employes to wear glasses while on duty?" He found that out of 112 roads reported, 77 required some kind of systematic eye and ear examination of those employes actively engaged in running trains and in giving and receiving signals. Twenty-nine of these roads required such examinations to be made by regularly appointed railway surgeons; thirty-one allowed various kinds of instructed railway employes to make examinations; nine roads sent doubtful cases to an eye and ear surgeon; sixteen required examinations to be made by regularly appointed eye and ear surgeons; four allowed such examinations to be made by the medical director of railway relief associations.

Mules' Operation, with Cases. The author of this paper, Dr. Frank C. Todd, of Minneapolis, Minn., called attention to the various operations employed as substitutes for enucleation and called attention to the operations of Mules, Frost and Lang. The failures in Mules' operation are due to escape of the globe, sympathetic inflammation, and irritable stump. He quoted the valuable statistics of Dr. G. E. de Schweinitz on this subject. Among the conditions causing failures and especially escape of the globe are: Hemorrhage, sepsis with consequent sloughing, imperfect or non-coaptation of the sclera, not enough sutures and the too early wearing of a prosthesis. Moist dressings are not advisable, as they promote suppuration. He sterilizes the ball in hot water, carefully examines it as to size and admissibility into the scleral cup. There is so little vascularity of the sclerotic coat, that union does not very easily take place. It is best to wait a month before employing a prosthesis.

Discussions.—In the absence of Dr. Fox, of Philadelphia, Dr. F. Allport, of Chicago, Ill., opened the discussion. He stated that ophthalmic surgeons are usually anxious to completely fill the scleral cup while a slack of scleral tissue should be left. He never uses a large globe. He inserts plenty of stitches into the sclera, not a certain definite number, but as many as the sclera will hold. He follows the suggestion of Dr. Prince, of Springfield, Ill., by swabbing out the scleral sac with 95% carbolic acid followed immediately by alcohol. He waits until hemorrhage has practically ceased before inserting the glass globe and controls the hemorrhage by very hot bichloride solution and then wipes out the scleral cup with iodoform gauze. He does not like the aluminum globe, neither does he use adrenalin on account of its reactionary results. Dr. M. Black, of Denver, Col., has abandoned Mules' operation, and has used the Snellen eye with just as good results. He prefers even filling the scleral cup with wax and thus believes that all the disadvantages resulting from a Mules' operation are removed.

The Inverted Image and Mirror Writing. This paper was read by Dr. Hale, of Chicago, whose name was omitted from programme by mistake. The author discussed the various theories advanced concerning the inversion of the image and mirror writing. He states that the theory that the image is transmitted by a special fibre to the brain, and that the upper portion of the retina was depicted on the corresponding lower portion of the brain and vice versa, cannot be accepted either by physiologists or psychologists. While the phenomena of vision are well known, the reproduction of the visual impressions is what particularly interests us. Mirror writing is not a pathological process, *per se*, but is frequently found in healthy children. Mirror writing especially has been more studied in the motor sense than in the psychological sense. The adult mind has acquired how to associate tactile sensation with visual impressions as is exemplified by difficult movements that can be co-ordinately made before a looking-glass. The paper was treated throughout with due regard to physiological and psychological factors. The paper was discussed by Drs. Savage, Weymann and Hale.

Report of Two Cases of Orbital Surgery by Dr. Adeline Portman. The paper comprised a report of the insertion of a glass ball into the orbit sometime after the enucleation

of the eye. Also a case of transplantation of mucous membrane into the orbit for cicatricial deformity, following a burn.

The Newer Pathology of the Retina, with Special Reference to the Changes Produced in the Ganglion Cells by Certain Toxic Agents, by Dr. H. Friedenwald, of Baltimore, Md. The paper embraced the consideration of the various pathological changes caused by toxic agents and the microscopical appearances described by Nissi, as well as original investigations upon animals made by the author by feeding them with toxic substances.

Atrophy of the Retina by Dr. D. S. Reynolds of Louisville, Ky. The author reports two cases of atrophy of the retina unassociated at first with ophthalmoscopic changes. In one case beginning with headache, failing of vision, loss of color perception, and latter progressive contraction of the field with central scotomata. The patient at last could not recognize any objects. The second case began with failing of vision that no glasses would improve, and later on contraction of the field and central scotomata and atrophy of the retina.

A Case of Blindness Due to Drinking Bay Rum Compared with Reported Cases Due to Methyl Alcohol and Jamaica Ginger.—Dr. H. Moulton of Fort Smith, Ark., the author of this paper, reported twelve cases of methyl alcohol amblyopia compared with eight reported cases of Jamaica ginger amblyopia, and identity of symptoms and ophthalmoscopic findings pointed out. In recently reported cases of essence of ginger poisoning the toxic agent is wood alcohol or its deodorized product, Columbian spirits. Jamaica ginger essence not considered poisonous until Columbian spirits came into use. Report of a case of blindness due to drinking bay rum.

Complete Recovery from Double Neuroretinitis, Clinically Resembling Albuminuric Retinitis, in a Case of Prolonged Hematuria, with Symptoms of Bright's Disease. Dr. C. A. Veasey, of Philadelphia, Pa., reported the case of a woman, aged thirty-five, who had for eight months persistent hematuria, vertigo, dyspnea and loss of weight. There was occasionally edema of the legs and moderate cardiac hypertrophy. Ophthalmoscopic examination showed the typical stellate white figure in the macular region. The fields were slightly contracted for form and color, but there were no scotomata. Examination of the urine showed considerable blood and albumen, but no casts. Examination of the blood showed mild secondary anemia. The patient was placed on a strict milk diet and Basham's Mixture, after which she gained in weight, and nine months from the time of the first examination no ophthalmoscopic signs of the disease remained nor any loss in visual acuity or contraction of the visual field.

The Election of officers was as follows: Chairman, Dr. Frank Allport, Chicago, Ill.; Secretary, Dr. C. A. Veasey, Philadelphia, Pa.; delegates to the House of Delegates, Dr. J. A. Lippincott, Pittsburg, Pa., and Dr. H. V. Wuerdermann, Milwaukee, Wis.

SECTION ON NERVOUS AND MENTAL DISEASES.

FIRST DAY JUNE 16, 1901

H. A. Tomlinson, M. D., of St. Peter, Minn., Chairman.

Address of the Chairman: Dr. Tomlinson spoke on the subject of **The Relation of Nervous and Mental Diseases to General Medicine.** He called attention to the close relationship between somatic disturbances and chronic nervous disease, and stated that while the symptoms manifested may have their origin in a destructive or degenerative process in some part of the nervous system, the real disease, upon the cure of which the ultimate recovery of the patient depends, has its existence in the vegetative organs. He said it may be safely asserted that all disease processes begin as intoxications, and that this is so even with chronic degenerative processes in the nervous system. During ten years of careful observation of the phenomena connected with the development and manifestations of insanity, in more than three thousand cases, he has never failed to find intoxication; either the result of im-

perfect elimination, or failure in the process of digestion and assimilation. Failure in elimination is most common, and involves most frequently the kidneys, then the lungs and skin. **Etiology of Paretic Dementia:** By Dr. Frank P. Norbury, of Jacksonville, Ill. He stated that the lesion of paretic dementia is a diffuse parenchymatous atrophy of the nerve cells, and partly, at least, of the neuroglia. The process is essentially chronic and involves more or less the whole of the cortex, even extending to the basal ganglia and cord. The question of the cause of this now well recognized degeneration is still in dispute, but in the light of the accumulated knowledge of to-day we find syphilis paramount as an etiological factor. In fact, it is the one factor—the primary factor, and with Dana we can say that “if there were no syphilis there would be no paretic dementia.” It is not, in truth, a syphilitic disease, but a para-syphilitic disease due to the effects of the syphilitic poison. In an etiological study of about 200 cases of paretic dementia, the author obtained a history of syphilis in fully 60%. His conclusions were as follows: 1. Syphilis is the chief factor in the causation of paretic dementia. 2. Infectious fevers, with their toxic influences, are contributing factors. 3. Heredity is a potent factor. Dr. Sydney Kuh, of Chicago, said there was much evidence to show that syphilis is by far the most important etiologic factor both in paralytic dementia and in that other disease which is so closely related to it, namely, tabes. Whether or not syphilis is the only etiological factor it is impossible to say to-day. We should recollect that in countries where syphilis is common, paralytic dementia and tabes are very rare, but this cannot be used as an argument either for or against the theory that there is a connection between the diseases mentioned. Dr. Edward E. Mayer, of Pittsburg, thought the claim that paretic dementia was dependent upon syphilis should be based upon a more scientific basis. Because a patient with paretic dementia has had syphilis, we should not take it for granted that syphilis is the etiological factor. Many years have usually elapsed between the occurrence of the two diseases, and the lesions of syphilis have not been found at post mortem in cases of paretic dementia. **Symptomatology of Cerebral Hemorrhage:** Dr. F. Savary Pearce, of Philadelphia, said that under the head of cerebral hemorrhage we include not only an extravasation of blood in or about the brain, but also thrombosis or emboli producing symptoms of acute softening; it is difficult to differentiate the latter condition from a slow exudation of blood within the encephalon. The symptoms of a typical case of cerebral hemorrhage are divided into those of the acute stage and those of the later, or chronic stage. While the patient may have some premonitory signs, such as dizziness, headache and dulness of mentality for some days or weeks before the onset of the attack, still it is the rule that he is feeling particularly well immediately preceding the apoplexy. The attack, in the majority of instances, occurs during the sleeping hours of the night. This is probably explained by the fact that inhibition generally is lessened during the early hours of the morning, and very likely there is much less resistance within the encephalon, thus allowing over-distension of the cerebral vessels, which produces the “breaking strain” in sclerosed cerebral arteries. If the hemorrhage has been massive the patient will be found comatose. The conjugate deviation will occur towards the affected side. Other symptoms are the unequal dilatation of the pupils, temporary abolition of the reflexes, the peculiar breathing, and the difference in the temperature between the two sides of the body. The paralyzed extremities may be hyperesthetic. If the patient is to recover, the temperature drops at the end of four to six hours, the pulse will become softer, its frequency will be but slightly above the normal, and the flushing and cyanosis of the face will disappear. Dr. Hugh T. Patrick, of Chicago, said the common belief that cerebral hemorrhage is apt to occur more frequently during the

sleeping hours is not based on facts and has been disproven a number of times. Dr. F. W. Langdon, of Cincinnati, said he agreed with the statement made by Dr. Patrick regarding the frequency of cerebral hemorrhage at night. An attack coming on during the sleeping hours, is more apt to indicate thrombosis than hemorrhage. The former accompanies low blood pressure; the latter high blood pressure. Dr. John Punton, of Kansas City, referred to the importance of coma as a prognostic condition in cerebral hemorrhage. The longer the duration of the coma, the less chance has the patient to recover. The symptom of coma should also receive more attention in studying cerebral hemorrhage from a surgical standpoint. Dr. Punton called attention to the fact that hemorrhage of the brain not infrequently occurs much earlier in life than formerly. The text-books teach that it is a disease occurring rather beyond middle life, usually between 50 and 60. The speaker said he had seen several cases which occurred between the ages of 30 and 35 years. **What can be done for the Epileptic in a Medical Way?** Dr. Robert H. Porter, of Chicago, presented a paper with this title. He said that the utter hopelessness with which the epileptic is usually regarded has retarded very much the proper study and treatment of the disease. A thorough and careful examination of the patient should be made in every case, in order to discover, if possible, the primary origin of the disease, the exciting cause and any complications that may exist. The speaker said he favored the theory that the primary origin of idiopathic epilepsy was due to a degeneration of the cells of the central nervous system, resulting from impaired nutrition. When these brain cells, with their impaired or perverted nutrition, are excited or greatly stimulated, they produce incoordination or perverted functional activity. Dr. Porter next referred to the strong physical element present in some cases of epilepsy. Whatever serves to stimulate the brain circulation, such as excitement, worry, hard study or close mental application usually increases the severity and frequency of these attacks. Remedies that stimulate the brain or produce an increase in the blood pressure generally have the same effect. On the other hand, the various measures that diminish the brain circulation and reduce the blood pressure aid greatly in controlling the seizures.

In the treatment of epilepsy, the speaker said, it is a well known fact that a mental impression is often sufficient to arrest the convulsion, even in the worst cases. Dr. Lambert Ott, of Philadelphia, said he had listened to Dr. Porter's paper with rapt attention, hoping to hear of some new remedy for epilepsy, but he was disappointed. The speaker said that after a large experience with this disease he had come to the conclusion that we possess absolutely no remedy which cures epilepsy, and we have but one which influences the epileptic seizures decidedly, and that is the bromide of potassium. Dr. Kuh said that various theories have been advanced regarding the cause of the epileptic seizure, but the subject is still in doubt. The experiments that have been made have given absolutely conflicting results. Some claim that hyperemia of the brain is the cause; others, anemia. Dr. Riggs said that while a discussion of the subject of epilepsy was a good field for mental gymnastics, it was not very profitable. He was not in sympathy, however, with the trend of opinion that nothing can be done for these patients. With use of the bromides, and proper attention to the digestion and elimination, as well as the correction of the habits of life, much can often be accomplished. One cause of failure in the treatment of epilepsy is that the patients are not kept under observation long enough. Dr. S. Savary Pearce, of Philadelphia, said he believed in the general systemic treatment of epilepsy, and the correction of all reflex causes of irritation. The speaker said that in a number of cases during the past winter he had given the fluid extract of *soianum carolinense* (horse-nettle) in fairly large doses with apparently good results. Dr. C. A. Drew, of Massa-

chusetts, said he thought the epileptic seizure was partly due to irritants circulating in the blood. He did not regard the reflexes as the basal cause of epilepsy, but he believed that all sources of reflex irritation should be corrected. His experience with bromides has not been very encouraging.

SECOND DAY, JUNE 5th, 1901.

The Treatment of the Acute Psychoses in Private Practice. By Dr. C. Eugene Riggs, of St. Paul. The essayist said that since the representative medical schools have introduced a course of Psychiatry as an essential part of their curriculum, the attitude of the profession has radically changed with reference to insanity. It is now believed that no person ought to be sent to an institution who is a suitable subject for home treatment. Dr. Riggs said he was convinced, as the result of a large experience, that home care in properly selected cases (by home care meaning either in a private family or private hospital) would materially shorten the length of an attack. He said there could be no question that the association of the insane with each other not only added greatly to their suffering as the result of personal contact, but that auto-suggestion intensified and prolonged indefinitely the morbid mental state. It is the absence of these conditions, together with the opportunity for individualization of treatment which makes home care so desirable and successful. **Dr. Richard Dewey**, of Wauwatosa, Wis., said the general practitioner very seldom considers for a moment the possibility of keeping an insane patient at home. The speaker said he had seen such patients who might well have been cared for in their own homes sent away to institutions. Generally speaking, however, such cases are better taken care of in proper institution than they could be at their homes or in general hospitals. A physician who has not had the opportunity of studying this class of patients is apt to fail in appreciating the necessities of the case. **Dr. Punton** said in the treatment of any form of acute psychosis he is a firm believer in the importance of absolute isolation of the patient, whether the treatment is carried out at home or away from home. Many general practitioners cannot realize the importance of this measure and make all sorts of compromises with the family which prove harmful to the patient. Acute insanity rapidly passes from a curable to an incurable stage, and it is upon our treatment during the first three months that the patient's chance of recovery largely depends. **Dr. J. G. Biller**, of Cherokee, Iowa, said he differed somewhat from the writer of the paper in regard to treating cases of acute insanity at home. Such experiments usually result disastrously, and generally speaking, the sooner the patients are removed from home, the better their chances of recovery. Such patients require constant, intelligent and careful watching, and this they can only get in a well kept hospital. **Dr. F. W. Langdon**, of Cincinnati, said he had been obliged to treat a number of cases of acute psychoses outside of institutions, and a fair portion of these terminated favorably. We know, however, that the environment of a patient in which his abnormal state developed is not the best for his recovery, and while under exceptional circumstances such cases may be successfully treated at home, the wisdom of this course is open to doubt. **Dr. Harold N. Moyer**, of Chicago, said that while he was in accord with the general consensus of opinion that cases of acute psychosis are best taken care of in general special institutions, there are some families who will not consent to having the patient removed from home, and under those circumstances we must do the best we can. **Nervous Manifestations of Syphilis of the Brain:** **Dr. Hugh T. Patrick**, of Chicago, read a paper on this subject, in which he enumerated the various popular fallacies regarding cerebral syphilis and described the most characteristic and important traits of the disease. **The Psychoses in Cerebral Syphilis:** **Dr. Richard Dewey**, of Wauwatosa, Wis., read a paper on this subject. He said

that in connection with it, several questions arise which must be taken into consideration. One is, the evidence of syphilis. Another, the very frequent existence in these cases of causes other than syphilis which have their share in determining the mental state, such as alcoholism, senile changes, arterial disease, kidney and heart disease and tumors of non-specific origin. The speaker gave the following statistics as the result of his personal observation: Among 1200 cases of all forms of nervous and mental disease he found 45 cases of well-substantiated constitutional syphilis. There were doubtless many more, which were rejected because the history of syphilis was not positive. Of the 45 cases in which there was an undoubted syphilitic history, 17 were diagnosed as paresis; 12 as cases of syphilitic brain disease with symptoms of an organic lesion; seven were cases of psychosis with marked delusional characteristics and without symptoms of brain syphilis; four were cases of hypochondriacal melancholia and two were cases of tabes with emotional symptoms. In addition to the above there was one case each of dementia, (slight), melancholia, and dementia paralytica of the senile type. **Dr. C. B. Burr**, of Michigan, said there were two interesting varieties of cerebral syphilis, accompanied by marked disturbances of the mental operations. There is one in which the motor symptoms predominate: the other, in which the symptoms are altogether psychical. In the one the symptoms are clinically difficult to distinguish from those of parietic dementia. However, there is apt to be expansive delusions, remissions are more frequent and the disease is of longer duration. Both varieties are characterized by reduction, this being their most conspicuous quality. In the second variety there is psychical reduction, manifested in dementia, the symptom of loss of memory being the most prominent. There is also hebétude and the patient is dull and unresponsive. **Suggestions for Lessening the Frequency of Relapse After Treatment of Morphinism:** **Dr. A. J. Pressey**, of Cleveland, spoke in favor of the gradual reduction of the amount of morphine taken, but he reduction must be so effected that the patient will feel better during the entire course of the treatment than he felt while he was taking the drug *ad libitum*. The quantity of morphine taken by those addicted to this habit is usually largely in excess of what is required to make them comfortable. It can, therefore, usually be reduced immediately by at least one-half. From that time on **Dr. Pressey** administers the drug four times daily, reducing the dose very slightly each day until it is as small as 1-120th of a grain, and even smaller in some cases. The morphine should never be discontinued entirely while the dose is still so large that its withdrawal will be felt by the patient. No set rules can be laid down to govern all cases. Each case must be treated according to the indications. In addition to a gradual reduction of the morphine, the patient should be given nerve tonics. Static electricity is also very beneficial. **Dr. T. D. Crothers**, of Hartford, said that the method of reduction in a case of morphinism, whether rapid or slow, can only be decided by the status of the individual case. The speaker said he had seen cases where a rapid reduction of the drug proved entirely satisfactory. After a patient who has been accustomed to take from ten to twenty grains daily is reduced to one grain, the drug can usually be withdrawn entirely without causing much discomfort, or some other alkaloid substituted if necessary. The greatest difficulty in the treatment of these patients, **Dr. Crothers** said, was to overcome the fascination of the hypodermic needle. **Dr. John Punton**, of Kansas City, said that the majority of persons who are slaves to morphine are usually suffering from mal-nutrition and are greatly reduced in flesh as the result of the habit. On this account, attention to the nutrition of the patient is just as important as the withdrawal of the drug. **Injuries, Feigned and Real, with their Differentiation and Medicolegal Aspect:** **Dr. Lambert Ott**, of Philadelphia, divided injuries into two classes:

1. Those with visible signs and symptoms.
2. Those with invisible symptoms.

Thes peaker referred to the frequency with which corporations are mulcted for heavy damages. With the increased number of accidents incident to modern methods of transportations this abuse has grown to such an extent that many of the larger corporations even pay unjust claims rather than submit the question of liability and damages to a prejudiced jury. The speaker referred to the frequency with which a verdict in these cases is the result of testimony given by biased or mercenary men. He spoke of the opprobrium which now rests on medical and expert testimony and concluded his paper with a plea for the more thorough and scientific examination of injured persons, so as to discover whether the symptoms of which they complain are real or feigned. Dr. Leo M. Crafts, of Minneapolis, said he would not agree with the reader of the paper as to the common occurrence of malingering by persons who have been injured, and the frequency with which corporations are mulcted. The statement that the plaintiff is more likely to be influenced by a moneyed consideration than the other party certainly does not obtain in the West. Dr. Richard Dewey said the even a patient who is perfectly honest may complain of certain symptoms which are not genuine. This has been observed in cases where there is no question of damages or suspicion of fraud. Dr. J. G. Biller said that several times in the course of his professional career he had been imposed upon by persons who claimed that they were suffering from certain symptoms as the result of injuries received, and who immediately recovered when their claim for damages was paid.

THIRD DAY, JUNE 6th, 1901.

Treatment of Neurasthenia: By Dr J. G. Biller, of Cherokee, Iowa. The speaker said that as the nervous system controls the organs in the body, and as these in turn affect the nervous system, it was no easy task to tell whether the neurasthenia was the result of disturbed bodily function or of a disturbance in the nervous system itself. The first requirement, in the treatment of a case of neurasthenia, is to make a thorough examination. Even if we accomplish nothing else by this, it will at least aid us in gaining the confidence of the patient, which is perhaps the most important element in bringing about a cure. Proper feeding is another important element of the treatment, and one that is often neglected. A plain, nourishing diet is preferable to the prepared or concentrated foods. On the other hand, some of these patients are suffering from over-feeding, or improper feeding. In addition to regulating the diet, we should see that these patients get plenty of sleep. Sulphonal in small doses may be necessary to induce sleep; if so, the drug should be dispensed by the physician himself and the patient should be kept in ignorance of its nature. A change of scene may prove beneficial in some cases, but not infrequently it does harm. As regards drugs, they should be sparingly used. We should not depend on the so-called tonics. The best remedies are those that assist the digestion and increase the activity of the liver. Small doses of calomel at intervals often prove beneficial. **The Psychoses of Chorea:** Dr. Harold M. Moyer, of Chicago, read a paper with this title. The following were his conclusions: 1. A well-marked alteration of the character and mentality can be noted in the majority of cases of chorea, usually preceding by some weeks the onset of the choreic movements. 2. Distinct hallucinatory phenomena are present in a considerable number of cases, which are not, however, of sufficient severity to merit being called a distinct psychosis. 3. The mental disturbance in chorea usually comes on after the choreic movements, but it may precede them. 4. The type is usually maniacal, though it may be melancholic, or present the character of acute delirium. 5. Mental disturbances are commoner in older children; they are rarely observed before the 12th year. 6. Chorea which are ac-

companied by mental disturbance later in life are almost always accompanied by organic changes in the central nervous system. 7. The prognosis is favorable where the mental disease complicates a simple acute chorea of Sydenham. **Dr. Augustus A. Eshner**, of Philadelphia, reported **Three Cases of Paralysis of the Serratus Magnus and the Trapezius. Mirror Writing and Inverted Vision:** **Drs. Albert B. Hale and Sydney Kuh**, of Chicago, presented a paper upon this subject, which was read by Dr. Kuh. They discussed the optics of the retinal image and the various theories that have been advanced in explanation of mirror writing and inverted image. The authors, in the main, agreed with the theory that the phenomena were the result of a disturbance in the co-ordination of the eye-muscles. While this is the most important factor, it is not the only one. If any one of the factors that aid us in forming a mental picture of an object is disturbed, a faulty image must of course result. **Fear as an Element of Nervous Diseases and its Treatment:** By Dr. John Punton, of Kansas City. The speaker stated that morbid fear is a common and potent element of nervous disease. In the treatment of this factor, we must take cognizance of both the mind and body of the patient. First, we must endeavor to gain the confidence and full control of the patient, and study the cause of his morbid fear. Isolation is essential, preferably away from home, but the isolation in on locality must not be too prolonged; otherwise, the patient will become too well acquainted with its new surroundings. We should endeavor to restore to the will its normal control of the emotions and intellect, and teach the patient to become more self-reliant. If the general health is impaired, proper medication is indicated. In addition to this, the judicious use of baths, massage and electricity in its various forms will prove beneficial. **Dr. W. A. Jones**, of Minneapolis, reported **Ten Cases of Multiple Neuritis** which came under his observation in the city of Minneapolis between the 15th of February and the 15th of March of the present year. Six of the ten case occurred during one week. Two of them proved fatal. Some of the cases corresponded with the usual description of multiple neuritis, while others closely simulated Landry's paralysis. The influenza bacillus was regarded as the etiological factor. **A Case of Localized Amnesia, with Remarks Thereon:** By Dr. Edward E. Mayer, of Pittsburg. The case reported was that of a young man, who was born in Pennsylvania in 1800. In 1884 he was on a railway train which was wrecked. He felt himself hurled through the air and then his mind became a blank. He has no recollection or knowledge of anything that occurred during the five years following the accident, and no one could be found who can give any information about him. Twelve years ago, that is, in 1889, he first came to Pittsburg and met his present wife, and two years later married her. He was never able to give her any information regarding his previous life, although he had not forgotten his name. Nine years ago, shortly before the birth of the eldest of his four children, he wandered away one Sunday afternoon and did not return until Monday evening. Upon his return home, he could offer no explanation for his absence. As he was a total abstainer, it was regarded as very peculiar. About a year later he again disappeared for several days, and during his absence he wrote a postal card to his wife, telling her that the memory of his mother had suddenly returned to him and he had gone to pay her a visit. He returned home a day or two later. The man's occupation, before he met with the railway accident, was that of a carpenter; subsequent to his marriage, he was employed at different times as a farmer, stock raiser, and painter. At this time he complained of symptoms which were regarded by his physician as evidences of a hepatic abscess. In February, 1901, while suffering intensely from abdominal pain, he fell to the floor and remained unconscious for several hours. When he regained consciousness, the memory of the last seventeen years of his life was apparently entirely obliterated. His mind had reverted to the time

previous to the accident. He insisted that he was 24 years old, and had neither wife nor children. The surroundings among which he had lived for the past twelve years were apparently strange to him, and it required much persuasion to induce him to believe the story of the true state of affairs. From that time on all his symptoms of hepatic abscess disappeared. He tried to resume his work as a carpenter, but had forgotten all about it and was obliged to begin as an apprentice. On March 8th of the present year he disappeared for twelve hours, and upon his return home he stated that he had walked about thirty miles in the country. The following day his wife gave him \$25.00 with which to buy some groceries. He failed to return home and no trace or word has been received from him since. **Dementia Following Inebriety:** Dr. T. D. Crothers, of Hartford, read a paper on this subject, in which he dwelt strongly upon the dangers of steady moderate indulgence in alcoholic stimulants. He stated that steady drinking, even without intoxication, was injurious, and the so-called "moderate drinker" was certain to suffer both physically and mentally from the practice. He said that the evidences of dementia were more often apparent in the moderate drinker than in the man who indulges occasionally to the point of intoxication and then sobers up and regains his mental physical balance. The life of the moderate drinker becomes more and more automatic. He has less spontaneity; less originality. He cannot adapt himself to new conditions with the necessary energy and judgment. His digestion becomes impaired, and this results in defective nutrition. He suffers from a spirit of unrest; there is a constant craving for excitement and change. There may be a craze for powerful drugs, which is a form of dementia; sometimes there is a craze for travel or for gambling and many forms of immorality. **The Importance of Heredity as a Cause of Insanity:** By Dr. Arthur McGugan, of Kalamazoo. The reader said that according to his observations 95 per cent. of the insane had a family history of impaired mental or physical health. In only a small percentage of cases was insanity due to physical or mental stress apart from hereditary weakness. Dr. Leo. M. Crafts, of Minneapolis, reported a case of **Persistent Brachial Neuralgia** resulting from a hypodermic injection in the wrist. He also reported a case of **Incipient Lateral Sclerosis, with Recovery.**

Election of Officers: The following officers were elected for the ensuing year:

Chairman, Dr. J. T. Eskridge, of Colorado.
Secretary, Dr. F. Savary Pearce, of Philadelphia.
Members of the House of Delegates.

The retiring Chairman, Dr. H. A. Tomlinson, of Minn.
Dr. Harold N. Moyer, of Ill.

A Case of Simultaneous Extra- and Intra-uterine Pregnancy. L. N. Varnek (*Medicinskoje Obosrenie, February, 1901.*) after pointing out the rarity of the condition, reports a case of a widow, 34 years old, multipara, who presented obscure pelvic symptoms which lead to a diagnosis of double salpingo-oophoritis. Severe hemorrhage supervening, she was treated with hot douches, ergot and hydrastis without, however, any marked benefit. These symptoms together with the appearance of a swelling on the right side of the uterus gave rise to a suspicion of **tubal pregnancy** which was confirmed by the admission of the woman that such a condition was possible. The simultaneous enlargement of the uterus however, still obscured the diagnosis, and an exploratory laparotomy was decided upon. The operation disclosed a **pregnant uterus** of 6 months and a **ruptured tube** filled with old blood clots. The tube was removed and the uterus returned into the abdominal cavity. The woman made an uneventful recovery and was delivered at term of a healthy child. The noteworthy feature in this case is the resistance of the pregnant uterus to the action of hot douches, ergotin, hydrastis and the surgical intervention. [A. R.]

TWENTY-SIXTH ANNUAL MEETING OF THE AMERICAN ACADEMY OF MEDICINE.

Held at the Hotel Aberdeen, St. Paul, Minnesota.

June 1-3, 1901.

SECTION ON MEDICINE.

The meeting called to order by the President, Dr. S. D. Risley of Philadelphia.

A short Executive Session was held. Forty-two new members were elected. The Nominating Committee was appointed as follows: Drs. L. Duncan Bulkley of New York; Dr. Thomas D. Davis of Pittsburg, and Dr. G. Hudson Makuen of Philadelphia.

The scientific business was then taken up in open session.

THE FIRST YEAR MEDICAL CURRICULUM.

Dr. Thomas D. Davis of Pittsburg, Pa., presented this paper. He said there had been great changes in the curriculum of the academical departments of all our institutions of learning—changes—not advances. He did not agree that many of the changes had been improvements in education. It would appear that the courses in arts and sciences had been arranged mainly to give a short cut into the profession rather than to broaden and deepen the foundations of true mental development. It is his conviction that no plan surpasses for true professional education foundation the old severe classical course, particularly valuable in developing the judgment and reason and forming the habits of application and mental concentration. Anything that cannot show its advantages in dollars and cents has been placed in the background. He impressed the importance of the subjects taught in the last two years of a college course, and believes that the first year course of a medical school should approach the last year course in a college. A four year medical course is not of itself an advancement in medical education. An entire re-arrangement of the curriculum in our medical schools is necessary to correspond to the four years required. Rhetoric could be taught with advantage. Botany should be taught, to give a more correct foundation for the vegetable materia medica. Logic, if not taught before, should be taught in our medical schools. In no way it was stated, could the practice of medicine be improved more rapidly and thoroughly than by training men to think, judge, and decide logically.

Psychology or mental philosophy were mentioned as of greater importance than all. The intimate mysterious relation of the mind to the body have been recognized, but the laws governing the mind and the many phenomena that have been observed and classified are, to a great extent unknown to medical men. The physician who fails to recognize and use mental influence loses a mighty power, yet our medical schools teach none of the laws of this influence. In the opinion of the author, a medical college offering a course for the first nine months which would embrace rhetoric, botany, logic and psychology, biology, osteology and general chemistry will, at the end of its four years course of nine months each, turn out far better equipped medical men than are to be found at graduation now. Under the present conditions a college graduate with three years in a medical school will be better posted in medicine and better prepared to practice it than a common school graduate can possibly be after four years in the same medical school.

Dr. Connor of Detroit believed that colleges of all kinds were committing a grievous wrong to their students in not having them taught so to write that they could be understood clearly and forcibly, as well as in not teaching them how to talk when upon their feet. Without this training they are handicapped. If necessary, this instruction should be put in with the study of anatomy and chemistry. Manual training in that their fingers might be able to follow out the students' preceptions was also advocated; as was

also "a little bit of business training" which would make the physician more prosperous, and more reputable in the minds of those in business circles. A number of physicians are wrecked because they lack business training.

Dr. Vaughan thought it a mistake that our students were not more frequently compelled to write theses, and that the abolition of the requirement was a backward step. Before a man studies medicine he should know mathematics through plain trigonometry. Also, the man who will get the best out of medicine must have a reading knowledge of French and German. He should have some knowledge of both Latin and Greek. The fact that a man has an A. B. degree may mean much or almost absolutely nothing. He thought it time that those interested in medical education in this country should force the literary school to give courses that properly lead to medicine. He expressed himself in sympathy with the law enacted by the New York legislature compelling every student to stay four years in a medical school, no matter what degree he may have.

Dr. Goldspohn of Chicago heartily endorsed Dr. Vaughan's sentiments in regard to a knowledge of French and German. While not judging England and all she represents in science, yet more original productions, more real contributions pertaining to pathological anatomy come from Italy and Switzerland, the smallest European governments, than we have from England herself in the last five or ten years. He felt that there is no possibility of a man keeping abreast with what the world affords unless he were a thorough student of German and French, from them getting the substance of what the rest of the world produces. A deficiency in the medical curriculum of to-day is the failure to appreciate the power of mind over matter, the want of a proper understanding of this psychological part of man. The amount of instruction in histology is grossly defective. He felt that a good thorough college course and then a four years medical course likely to do the most good.

Dr. Jackson of Denver, thought that the study of logic and psychology as carried on furnished a very poor outfit, or a very insufficient guarantee of a logical mind or an ability to apply psychological principles to general facts. In illustration, a base-ball or billard player learns to do a certain thing with perfect accuracy, promptness and ease, and yet knows nothing perhaps of the names or forms of classification or arrangement of the muscles by which he does it, still less of the nerve paths by which he accomplishes his purposes.

Dr. L. Duncan Buckley remarked that the crowning evil of medicine, the advertising drug business, was due to faulty education in our medical schools. Another fault was in too great a crowding from minutiae. He emphatically approved of the suggestion that students be required to write a thesis at the end of each year. He had seen too often in young men coming up for hospital examinations, a want of concentration of thought, and of logic.

"Is the Demand for Reciprocity Based upon Fact or Fancy?"

Dr. Charles McIntire of Easton, in this paper gave the results in the examination of reports of the various state boards of medicine examiners for 1900, in order to form an estimate of the comparative number of physicians who seek to move from one state to another. The figures quoted in the paper give the entire number examined, the number failing, and of those failing, the number who were not graduates of the last class. A tabulated statement showed that out of all 511 individuals, 292 could have had an opportunity of taking a state examination elsewhere. A considerable number failed, and were coming up for a second, only to fail again. It would be far from the truth to infer that of the larger number who were sustained in their examinations, the same proportion of older men presented themselves; at the same time, many such are in-

cluded in those who receive a license, and it will not be an overstatement to assume that the number of those who passed the examinations, who would have had the privilege of reciprocity extended to them, fully offsets the number who failed in the examinations, who had never made the effort to practice elsewhere. If so, there are at least 292 out of the total number examined who would have been able to avail themselves of the privilege of reciprocity, or about 7½ per cent.

"The Desirability of Reciprocity in Medical Licensure."

A paper with this title by Dr. J. N. Hall of Denver, was presented. An experience of six years on the Colorado State Board of Medical Examiners demonstrated that many physicians of excellent repute seek a residence in that State because of illness, either personal or otherwise. Though such men are fitted to practice medicine they are rusty on the details of the foundation studies. Reciprocity between States having stringent requirements would be of the utmost benefit to men of this type. Reciprocity, however, should not be established, except among those states where requirements are essentially equivalent.

Reciprocity in Medical Licensure from the Standpoint of a Physician who changes his residence.

Dr. Edward Jackson of Denver, in this contribution said that about one in every four or five physicians changes his field of practice from one state to another, at some time during his professional career. In making such a change the difficulty is not with the practical branches, but with passing the examination in what may be regarded as the preliminary studies,—chemistry, anatomy, etc. The physician who removes across state lines cannot justly be expected to keep better posted in those branches than the most of those who do not move. "Reciprocity" seems liable to be awaiting for others to do something rather than a practical measure of relief. The acceptance of the certificate of another state board, as evidence of a proper acquaintance with much preliminary studies, would remove the chief hardship. The main obstacle to this is fear of "lowering the standard." But the "Standard" in many states is already "so high" as to favor evasion and special legislation letting in all sorts of irregular practitioners and to threaten the permanence of laws regulating medical practice.

"Away with Reciprocity."

Dr. Charles McIntire in this paper stated that Reciprocity is an *ignis fatuus*, which will lead us far astray. Physicians already possessing the legal right to practice in one state, should have privileges, in removing to another state, not accorded to those who have not, as yet, been licensed to practice. These privileges must not be such as to act unfairly either to the people of the state or the physicians already practising in the state.

It is well to remember that those states which have medical practice acts at all worthy the name, divide into two classes—those which accept certain diplomas as the evidence of fitness; and, those which require an examination. In both instances the text is an educational one. The first class have no personal interest in this question, since they do not inquire into the personal knowledge of the applicant. In the very nature of the thought, there is concession in reciprocity which precludes the idea of strict equality. If we seek reciprocity we must seek to secure an agreement between the various boards, for each to accept without question the licenses issued by each other. Physicians already possessing the legal right to practice in one state, should have privileges in removing to another state, not accorded to those who have not, as yet, been licensed to practice. It might be said that the man distinguished enough to be called \$800 or 1,000 miles to occupy a professor's chair might be admitted upon his reputation. Unfortunately, were this done in one case, there would be the danger of pronouncing it reputation, but spelling it influence. Whatever privilege is given to the older man, a favor to him, must be fair to all concerned.

ADDRESS OF THE PRESIDENT, DR. S. D. RISLEY.

"Some of the Ethical and Sociologic Relations of the Physician to the Community."

Dr. Risley in his address showed that a most striking characteristic of the medical man is a sense of obligation to the community, that this ethical attitude finds expression, not only in the daily routine of his laborious professional service, but in a pronounced educational influence on all those lives which pertain to the healthfulness of the people and their socio-medical welfare; that this influence is signally exerted in the investigations and control of the relation which our defective classes sustain to the social body. Almost suddenly the student of social evolution has come to realize that through the altruistic spirit of our civilization a rapidly increasing percentage of degenerates have grown up in our midst, a fact which presents a serious and most complex problem for solution by the new century. Two suggestions are made for its arrest. First, the legalization of means to prevent propagation of defectives by asexualization; and, second, by a wider education of the community regarding the importance of selection in the marriage contract and its control by the State. To solve it wisely and humanely will require the best efforts of the churchman and the physician and the statesman.

SECOND DAY.

In the short executive session preceding the scientific business a few additional names were numbered with the fellowship, and the resignations of three accepted. Some slight changes in the by-laws were inaugurated and the Secretary called to the attention of the Academy the work of the *Bulletin*, the official organ of the body.

The first paper was entitled:

Abuses of Institutionalism.

by Dr. Eugene G. Carpenter of Columbus, Ohio. Dr. Carpenter stated in regard to institutionalism that it is an outgrowth of organization and is the result of routinism. Routinism it was declared develops prefunctionism, which in turn leads to automatism, differing little from that which is mechanical. That which is mechanical moves in fixed lines and is consequently opposed to progress. Too often the institutionalist is dominated by the institution. The true institutionalist, however, remains the master of the institution. The executive of the institution sets the pace for the other participants of the organization. The policy therefore should be broad and liberal. The preventive measures to the abuses, above every measure are to be kept in mind. These are found in the *individual equation* which goes to make up the warp and woof of the fabric. The institutionalist should glean everywhere for that which makes progress and gives to his labors the widest possible usefulness.

Tendencies in Hospitals for the Insane with Some Suggestions, was the name of a paper by Dr. Robbins of Danville. The paper was read by title. Dr. Hill was unable to be present owing to the additional duties devolving upon the staff members from the death of Dr. Johnson, whom it may be remembered was stabbed by a patient under treatment.

The Advantage of Civil Service Principles in the Conduct of State Hospitals for the Insane.

Dr. Gershom H. Hill of Independence, Iowa, and Superintendent of the Iowa State Hospital for the Insane in this paper treated of the benefits resulting from the system and underlying principles in having a board of three in control of the state institutions of Iowa, in practice for two and a half years. It was shown that the system was free from political influence. A careful supervision is had over the expenses of supplies. In the hospital under Dr. Hill's supervision, the personal element in the treatment of patients is preserved, and there is no interference with individually approved ways of treating patients. A medical society is held in connection with the hospital, scientific papers are read and discussed and a quarterly bulletin pub-

lished. Contributions are solicited from other institutions in Iowa and other states. Solicitation on the part of the board for the selection of an employé is counted a misdemeanor. It is the distinction of the board of control law to do the business of the state institutions on the same principles and methods used by the United States Government in buying supplies or by the up to date business man. The tendency is for the legislature to trust the board of control, to adopt their recommendations and to appropriate all the money asked for as the resources of the state will permit. Merit is the criterion in selecting help. The results under these civil service rules is to secure as nearly as possible perfection.

The Need of National Co-operation in the Establishment of Sanatoria for Tuberculosis.

Dr. A. Mansfield Holmes of Denver, detailed the advantages of sanatoria in that they increase the chances of recovery; afford an opportunity for rigid sanitary regulations among patients, and furnish a means of educating those infected, and the public, against sources of infection. He divided the varieties of sanatoria into three classifications: for patients of limited means; for those of moderate means, and for the well to do. The methods of conducting sanatoria were outlined under the purely charitable institutions; co-operative institutions, and those conducted for profit. In considering the location of the sanatoria, there should be for the incurable cases sanatoria located near large centers of population regardless of climatic conditions; for the incipient cases the most favorable climatic conditions should be chosen for the location of the sanatoria. Co-operative sanatoria established on the proper plan and wisely conducted would, in the author's opinion, overcome many of the present difficulties. State and municipal aid together with individual philanthropy could do much in this field.

"Evils in some Asylums, Hospitals, Infirmarys and Training Schools for Nurses that might be avoided by placing them under Civil Service Rules, and by Proper Requirements, Regulations and Inspections on the part of a properly constituted and authorized Board of Health in each State." Dr. Albert Goldspohn of Chicago, spoke on this subject, contending that many of these institutions did not yield their intended degree of usefulness because of too exclusively lay management and lay selection and appointment of medical men, which very frequently resulted in the appointment of inferior men. A still greater evil frequently occurred in the public hospitals and asylums that were under political influence. Many governors, county commissioners, etc., regarded medical appointments like all others as something with which they had a right to reward their political henchmen, who among doctors were generally of an inferior grade professionally. He advocated giving the State Boards of Health the additional duties, powers and emoluments of a medical civil service board; that this board should select and submit all the candidates for political medical appointments; that it should oblige laymen trustees of private or denominational hospitals, etc., to have their candidates for medical positions selected by some creditable local medical society; that it should determine the fitness of all superintendents and matrons of hospitals and license them for such positions, and that a representation of such a board should examine or inspect every such institution at least once a year.

"Hospitals and Sanatoria Founded, Owned and Controlled by the Medical Profession: A Case in Hand."

Dr. H. Bert Ellis of Los Angeles, stated in this paper that hospitals may be divided into three broad classifications: Charitable, private, and a hybrid class, where private wards and free beds are mingled for the pecuniary gain of the hospital. The description of a hospital owned and controlled by physicians is given. It is the outgrowth of a corporation known as the California Hospital Company. The first building erected for the hospital was soon found

to be inadequate and was added to. At present the hospital owns a corner property 323 feet by 185½.

Patients select any reputable physician and pay him for services. Every physician prescribes for and operates upon his patients as if in the patient's own home and prescriptions are filled at the drug store. Connected with the hospital is a training school for nurses. The absolute management of the Hospital is vested in a Board of nine directors elected annually from among the stockholders. The plan of the management is recommended to Eastern confrères because the construction of the building and the hospital service are entirely in accord with the desires of the physicians; patients realize that they are in a hospital controlled and practically owned by their own physician, which insures confidence; and whatever profits accrue from the hospital revert to the physician, thus giving safe investments. In the opinion of Dr. Ellis it is as essential that the profession own and control the hospitals and sanatoria as that they should own and control their medical journals in order to keep them as free as possible from commercialism.

"A Suppressed Educational Problem."

Dr. James L. Taylor of Wheelersburg, Ohio, urged in this contribution an enlightened "Natural Selection" in lieu of the ignorant, haphazard methods of selection among people, which result so generally in physical as well as intellectual deterioration.

"The Relation of the Clinical Laboratory to Its Hospital."

Dr. Henry W. Cattell of Philadelphia, presented a paper under this title, in which he takes for granted that the time has gone by when it is necessary to argue for the existence of a clinical laboratory in connection with a hospital. The questions to be considered in the internal administration of a hospital are the relations of the clinical laboratory to the board of managers, the medical and surgical staff, the chief resident physician, the resident physicians, the superintendent, the nurses, the out-patient department, etc. Questions such as these should be asked, discussed and answered. How shall the laboratory be built, equipped and conducted? Shall there be a laboratory attached to each ward, a general laboratory, or a combination of both? Shall the director and his assistants be paid for their work? What relations shall exist between the laboratory worker and the clinician. What are the usual causes of friction arising from the new state of affairs? Should the members of the staff be expected to bring urine, sputum, blood, etc., of their *pay* patients both in and out of the hospital and make the laboratory make these examinations free of charge? Shall original investigations be carried on in such laboratories? Shall the workers in the laboratory be permitted to perform and to charge for work received from their own patients or from those desiring such services for money?

From personal experience extending over a period of twelve years, and from an intimate connection with a number of hospitals in various capacities, Dr. Cattell gives his personal views in regard to the answers to some of these questions.

Dr. W. W. Keen of Philadelphia, said he was glad indeed to have heard the paper of Dr. Cattell. He was less interested, perhaps, in the clinical laboratory from the administrative point of view than from the scientific and surgical. He emphasized the statement that it was granted that at the present time every hospital, small or large, should have a clinical laboratory, and more than that, such a laboratory needs a larger field of usefulness, which in ten or twenty years would be doubled or even tripled. Dr. Keen emphasized also the fact that the poorest patient to-day receives better care in a well managed hospital than the well to do or even rich could get at their own homes.

"Necessity for Revising Medical Fees."

Dr. P. Maxwell Foshay of Cleveland read this paper, stating that the custom of charging a fixed sum for each

visit was a relic of antiquity and illogical. Other callings are differently regulated as is also the special practice in the profession. The author thinks there is every reason in the world for the general practitioner to proportion his charge in all cases to the value of the service rendered and to the ability of his patient to pay. The need of a "fee-bill" is stated to establish a standard agreed upon by physicians in their societies to which the profession can appeal when dealing with patients. This also is of definite service in court when suing to recover the amount of a bill.

A greater object urged for this new method is its means of checking to some extent the pernicious custom of giving "commissions." No present retrogressive tendency in the evolution of the medical profession is at present so strong as this of the physician dividing fees behind the patient's back. It saps morality to its foundations.

"Refraction."

A paper by this title was presented by Dr. James A. Spalding of Portland, Me. Dr. Spalding gave a personal experience of an ophthalmologist suffering from a sudden loss of vision and consulting first the optician and then the oculist for aid, showing the inefficiency of the former and the great help which the latter gave to him. In view of this Dr. Spalding asks, would it not be preferable for the profession to address the public through the public press regarding all sorts of ailments, thereby preventing them accepting the beguilements of charlatans. Physicians too ought to be careful in referring their patients only to those who have a proper knowledge of disease. An increase in the solidarity of the profession is needed.

Dr. Tuckerman of Cleveland, and Dr. Risley of Philadelphia, referred to cases in which grievous damage had been done through failure of the patients to be referred to an oculist rather than to the advertising optician.

The meeting at his point went into executive session. The Nominating Committee named the following officers who were elected:

President, Dr. V. C. Vaughan; 1st Vice-President, Dr. James L. Taylor, of Wheelersburg, Ohio; 2nd Vice-President, Dr. W. A. N. Dorland, of Philadelphia; 3rd Vice-President, Dr. H. P. Ritchie of St. Paul, 4th Vice-President, Dr. H. Bert Ellis of Los Angeles of Cal.; Secretary and Treasurer Dr. Charles McIntire of Easton; Assistant Secretary, Dr. A. R. Craig of Columbia, Pa.

After a few remarks by the retiring President, Dr. S. D. Risley, the meeting was declared adjourned.

A Case of Barlow's Disease.—Dr. G. Variet reports a case of infantile scurvy with pseudo-paralysis of both legs, in a boy of 7 months (*Bulletin et Mémoires de la Société Médicale des Hôpitaux de Paris*, 1901, No. 8). The child had been taking Gaertner's milk, which is cow's milk with half its casein deducted and lactose added, since the age of two months. He had no teeth. Upon diluted, unboiled milk and orange juice, the conditions cleared in two weeks. After a full review of the literature of the subject, Variet concludes that Barlow's disease bears no relation to adult scurvy; that it is probably hemorrhagic rickets; that it is very rare in France, though sterilized milk is very generally used; that modified milk rather than pure milk causes it; and that it is not a serious condition, as change of diet will effect a cure. [M. O.]

The Influence of Work, Nourishment, and Dust upon Tuberculosis.—Lannelongue, Achard, and Gaillard report their experiments upon 100 rabbits inoculated with tubercle bacilli, in the (*Bulletin Medical*, 1901, No. 36). The inhalation of dust-laden air proved fatal to 17 out of 20 animals. Those which were left alone at rest are still living, while those which did the most work died first. Insufficient food by itself hastens death from tuberculosis. But those animals died soonest which received but scanty food yet did hard work; they also showed great loss of weight. Whence they conclude that the emaciation often found with tuberculosis in man is the result of nutritive disturbances, especially alimentary, not of the tuberculous process. [M. O.]

8. Furunculosis of the External Auditory Canal Simulating Mastoid Periostritis. JAMES GALBRAITH CONNALL.

1.—In this clinical lecture J. C. Renton discusses the various forms of appendicitis and the established treatment of each. [J. H. G.]

2.—P. J. Freyer discusses the symptoms and diagnosis of stone in the bladder, kidney and ureter. Hematuria, although not the first or most distressing symptom of stone in the bladder, is usually the one which causes the patient to seek medical advice. It comes on gradually and toward the end of micturition. The amount of blood is increased by exercise. The stoppage of the flow of urine is not the most common symptom of stone, but occurs more frequently in the earlier than in the later stages. Attention is called to the fact that frequent micturition occurring from stone in the bladder takes place during the day when the patient is moving about. The author has operated upon over 1000 cases of stone and among these there were only 23 females. The author reminds us that other conditions than stone give rise to reflex pain at the glans, among these being enlarged prostatic middle lobe, tubercle of the prostate, local cystitis, ulcer of the bladder, clots of blood, etc. The pain of stricture when it does occur accompanies the act of micturition and is felt at the location of the stricture; pain of an enlarged prostate precedes the act and is as a rule referred to the hypogastric region; whereas the pain of a vesicle calculus follows the act of urination and is felt behind the glans. It must be remembered that prostatic enlargement and calculus are very frequently associated. In tumors of the bladder the bleeding is more profuse than in cases of stone, and the urine is uniformly mixed with blood. Tubercle of the bladder more closely resembles stone than any other condition. The sound and the cystoscope here will enable one to make a diagnosis. Always a rectal examination should be made before sounding. An anesthetic should always be employed in children. There is no better sound than that known as Mercier's. When all other means of diagnosis fail the author uses a method which he brought out a number of years ago which consists in introducing one of the canulae of the Bigelow apparatus into the bladder and applying the aspirator. Finally, Leiter's electric cystoscope will be found of the greatest advantage in making diagnoses of bladder conditions. The symptoms of renal calculus are next described. Renal colic occurs as a symptom when the stone is small, but after the malady has existed for some time, perhaps two or three years, the typical renal colic attacks gradually subside, to be replaced by a constant heavy aching pain fixed in the loin. Hematuria follows attacks of renal colic and rarely it occurs periodically as the first symptom noticed by the patient. As a rule the quantity of blood passed is not large. It is in the early stages that this symptom is most marked. Attention is called to the

fact that heredity plays a considerable part in the causation of stone. The Röntgen rays may be employed to form a diagnosis of stone but if no stone is found by this means one should not be deterred from exploring the kidney if the symptoms of stone are well marked. Stone in the ureter is next described and reference is made to the use of the cystoscope for the diagnosis of stones lodged in the lower extremity of the ureter. [J. H. G.]

3.—W. F. Adams reports 206 operations done in India for stone. The author used lithotripsy in 153 males and lithotomy in 36. He has never found a stone too hard to crush. 48 of the cases were in boys under 10 years of age, and 15 were in boys under 3 years of age. One death occurred in a boy 3½ years of age. The author derived great advantage from the introduction of a drachm of oil into the urethra prior to the passage of the instrument and in young boys the crevices of the crushing instrument were filled with soap before introduction to avoid scratching the mucous membrane. When the instrument cannot be readily and easily passed he thinks lithotomy had better be resorted to. Three deaths occurred out of 36 cases of lithotomy and three out of 161 cases of crushing. Two of these deaths could hardly be attributed to the operation, which was lithotripsy. [J. H. G.]

4.—Herbert T. Herring recommends moist heat as a method of sterilization of soft catheters. Water at 150 degrees F., even for ½ minute is a reliable sterilization for catheters for ordinary work (that is it would not in this time kill bacteria with spores, but these are not likely to be met with). The author then describes a metal case which he uses for heating and at the same time lubricating soft catheters. [J. H. G.]

5.—Monro reports the case of a man who died at the age of 46 years, with all his joints ankylosed. The disease began when the patient was 18 years of age. He was an iron turner by occupation and it is very probable that the disease was caused by frequent wetting, as the patient was going to and from his work. The course of the disease was very painful until the joints affected became fixed, and then the pain in that particular joint would disappear. The patient was obliged to give up work 2 years after the onset of the disease, and 2 years later became bed ridden. The right eye was the seat of an acute iridocyclitis, which rapidly went on to atrophy of the globe with subsequent ossification of the choroid coat. Death occurred during an attack of bronchitis and pleuritis from accumulation of bronchial secretion. There was no autopsy. The author considers the case to be one of universal bony ankylosis or arthritis ossificans. [J. M. S.]

6.—Keith Campbell reports a case of strangulation of Meckel's diverticulum which occurred in an old man 70 years of age suffering with senile dementia. The diverticulum was 4¼ inches long and was herniated into the left crural canal and here adherent to an inflamed gland. It closely resembled the small intestine but was smaller than this gut. Its proximal attachment was 2¾ feet from the ileo-cecal valve. In addition to the strangulation in the hernial sac the diverticulum was also twisted upon itself. No operation was done, the condition described being learned post-mortem. [J. H. G.]

7.—E. Donaldson reports a case of cancer of the larynx which ran over a course of 10 years. The case illustrates the fact that a warty benign growth may present symptoms of a benign tumor for a number of years and in the end become malignant. [J. H. G.]

8.—James Galbraith Connal reports two cases of furunculosis of the external auditory canal which gave rise to symptoms very closely resembling mastoiditis. In these cases without an examination of the canal one would have supposed them to be cases of periostritis of the mastoid. The swelling and edema of the mastoid area is due to the extension of the inflammation from the external auditory canal through the fissures of Santorini, or along the fibrous band in the roof of the canal. [J. H. G.]

LANCET.

May 25, 1901. (No. 4056.)

1. An Address on the operative Treatment of Abscess when situated on the Brain. CHAS. A. BALLANCE.
2. The Erasmus Wilson Lectures on the Pathology and Diseases of the Thyroid Gland. WALTER EDMUNDS.
3. The Surgical Treatment of Chronic Ulcer of the Stomach. A. W. MAYO ROBSON.
4. Analyses of Stools and Urine from Epileptic Patients under Treatment with "Brominol" compared with similar Specimens from Patients under Potassium Bromide. V. HARRISON MARTINDALE.
5. Two Cases of Carcinoma treated with Cacodylate of Soda. EDWARD MARTIN PAYNE.
6. Acute Colitis in Children. EDMUND CAUTLEY.

1.—Charles A. Ballance discusses in this address the operative treatment of abscess of the brain. He thinks that it is important to determine the nature of the micro-organism producing the abscess at as early a period as possible. The various details of operation from the sterilizing of the skin to the application of the dressing are minutely described. He recommends very strongly a large opening in the skull after first turning down a large scalp flap. For the drainage of an abscess in the temporo-sphenoidal lobe the trephine opening should be made 7-8" above the supra-meatal spine. In operating for a cerebellar abscess the trephine should be placed with its upper edge just below Reid's base line and its anterior edge touching the posterior border of the mastoid process. In incising the dura mater the opening should be made by a flap rather than by a crucial incision. Ballance recommends the use of a long, narrow, straight bistoury for the purpose of exploration rather than the use of the exploring needle or canula, as the incised wound of the brain heals better than the punctured wound. The finger is also to be used for exploration, irrigation of an abscess of the brain should only be done when there is free exit for the fluid such as is accomplished by the use of a tube. The author does not approve of tamponing these cavities with gauze. Recurrence of symptoms is not an uncommon thing a few days after the opening of a brain abscess and it is due either to a reaccumulation of the fluid or else to an entirely new formation of pus in another part of the same lobe. This is particularly true of the cerebellum.

[J. G. H.]

2.—Edmunds delivered three lectures on the pathology and diseases of the thyroid gland before the Royal College of Surgeons of England. He describes the histology of the thyroid gland stating that it is composed of closed vesicles lined with epithelial cells. The secreting cells are cubical and elaborate the colloid material, which may be readily detected by microscopical tinctorial tests. It has been demonstrated that the nerves of the gland are in close proximity to the secreting cells. He also states that the parathyroid glands, which are small glands in relation to the thyroid gland, are composed almost exclusively of cells, and that they do not contain vesicles and very little, if any, colloid material. Four of these glands have been described, one behind and above, and another in front and below each lobe of the thyroid gland. They are developed prior to the thyroid lobes. The parathyroid glands are with difficulty differentiated from accessory thyroid glands; the main point of difference being that the parathyroid tissue is composed almost exclusively of cells. Complete removal of the thyroid glands and the parathyroid glands in a dog is followed by well defined symptoms in forty-eight hours, and by death on or about the fifth day after extirpation. An early symptom is a fibrillar twitching of the muscles. General convulsions may occur. During these the temperature rises and the respirations are hurried. These seizures may last for about an hour and may recur.

In a day or two the animal becomes listless, the hair falls out, the animal has difficulty to maintain its equilibrium, the limbs later become rigid, the urine may contain albumin, less commonly sugar, and the temperature is sub-normal. Occasionally dogs recover after total extirpation of the thyroid gland. Removal of the thyroid gland in rabbits produces no effect whatever, for the reason, as Gley has demonstrated, that in rabbits two of the parathyroid glands are separated from the thyroid gland proper, and when the latter is excised these two structures escape removal. This observer also showed that when the parathyroid glands and the thyroid gland were removed the rabbit as a rule, died. Excision of the thyroid gland in monkeys produces symptoms which are almost identical with those seen in dogs, and that death nearly always occurs in these animals after removal. After some experiments Edmunds pointed out that thyroid-feeding in dogs, after excision of the thyroid gland, modified the symptoms somewhat and delayed death for a few days and decreased the mortality slightly. In monkeys similar results were obtained. Removal of two parathyroid glands and a single lobe of the thyroid in dogs was not followed by death, but a subsequent removal of the remaining thyroid lobe and its parathyroid glands was followed by a fatal issue. When but a single lobe was excised hypertrophy occurred in the remaining portion. If the thyroid gland and three parathyroid glands were removed in a dog, care being taken not to interfere with the blood supply of the remaining parathyroid gland, death did not occur as a rule, and no obvious effects followed. The parathyroid gland remaining became hypertrophied but did not develop into thyroid tissue,—vesicles did not form. The subsequent removal of this gland and two parathyroids was followed, by death. In rabbits extirpation of the thyroid gland and two parathyroids was followed after several months, by impairment of the health, falling out of the hair, and swelling of the lower part of the face. The palpebral fissure became very narrow. Complete parathyroidectomy leaving the thyroid lobes, in nine dogs, was followed by death in four animals, temporary symptoms in three, and no ill effects in two. The author emphasizes that it is very difficult to remove all of the parathyroid tissue. He refers to the conclusions of Vassale and Generali, who demonstrated that complete parathyroidectomy in dogs was followed by death. After excision of the parathyroid glands the thyroid lobes did not enlarge, but the secreting cells became columnar, the vesicles were filled with a watery secretion, and the colloid material diminished or completely disappeared. He maintains that the parathyroid glands probably secrete a material which is stored in the thyroid lobes, and that the thyroid lobes which are left after the removal of the parathyroids are in a state of what may be termed "compensatory hypertrophy." Excision of one thyroid lobe, in the five dogs which survived, after total extirpation of the parathyroids, produced death in two, and in the remaining three subsequently the other thyroid lobe was removed. Death occurred in one, and two survived and recovered after temporary symptoms. The symptoms developing in the animals that subsequently died, were great weakness, emaciation, tremors, narrowing of the palpebral fissure, unsteadiness of the gait, followed by paralysis of the hind legs. Seven dogs were subjected to partial parathyroidectomy;—one died after seventy-two days, and four developed symptoms from which they recovered. In one of the six remaining dogs the removal of both thyroid lobes produced death in three days. One thyroid lobe was excised in the remaining five dogs, and death resulted in three instances, while two recovered and one of these manifested definite symptoms. Finally, the removal of the remaining thyroid gland in the two animals that survived, produced death. Incomplete extirpation of the parathyroid glands, in two of the dogs was followed by a swelling of the palpebral fissure, and after a subsequent operation the eyes became narrowed and re-

tracted. In one of the dogs in which incomplete parathyroidectomy was performed, the animal developed no ocular manifestations, but the excision of one thyroid lobe and parathyroid gland in this animal produced a widening of the palpebral fissure. The author concludes that complete parathyroidectomy probably induces exophthalmos in the non-fatal cases, while in those instances in which death results, either from total thyroidectomy or removal of the parathyroid glands, the palpebral fissure becomes very narrow. The author emphasizes that these observations lend strong support to the view that the parathyroid glands are involved in Grave's disease. By a series of experiments he has demonstrated that the nerve supply of the thyroid gland has much to do with the control of its internal secretion. He excised a part of the supra-laryngeal nerve and a portion of the vago-sympathetic on one side, and removed the thyroid lobe with its parathyroid glands on the opposite side. Of nine dogs experimented upon three died, four of the remaining animals developed athyroidic symptoms, and the remaining two developed no symptoms. The author states that we must admit the possibility of disturbances with the nerve supply in the pathology of thyroid disease. Reference is made to the symptoms which result from the administration of large quantities of thyroid extract in man. He mentions the results of a number of observers who have shown that the administration of the thyroid gland produces: increase in the pulse rate and respirations, fever, sensations of heat and increased perspiration, tremors, increased secretion of urine, often albuminuria, and mental agitation. He fed dogs upon large quantities of thyroid extract without any obvious effect. In monkeys the administration of the thyroid extract produced exophthalmos, a widening of the palpebral fissure, dilatation of the pupils, emaciation and weakness, falling out of the hair in patches, and paralysis of one or more extremities. Seventy-six days was the average duration of life of the monkeys fed upon thyroid extract. The effects produced upon the eyes were undoubtedly due to the action of the thyroid extract upon the cervical sympathetics. He administered thyroid extract to two monkeys in which the cervical sympathetic had been excised on one side. After twelve days he found that on the unoperated side there was exophthalmos, dilatation of the pupils, and widening of the palpebral fissure; while on the other side the pupil was not dilated nor was the eye-ball prominent, and the palpebral fissure was narrow. The author states that very little is known in regard to the action produced by the administration of the parathyroid gland. With respect to myxedema and cretinism he is inclined to agree with the view set forth by Allen Starr, that the narrowing of the palpebral fissure cannot be attributed to the swollen condition of the eye-lids. Edmunds believes that the administration of thyroid extract is the best treatment for sporadic goitre. In regard to the pathology of Graves's disease evidence points strongly to the view that the symptoms are due to the secretions from the goitre. The thyroid gland, in cases of Grave's disease, appears to be in a state of active secretion. Microscopically, it has been shown that the secreting cells lining the vesicles are columnar instead of cubical, the colloid material within the vesicles is diminished or absent, and replaced by a secretion which reacts poorly to stains. These changes are practically identical to the compensatory hypertrophy in animals after removal of part of the gland, and finally he suggests that the primary lesion may possibly be found in the parathyroid glands. The article is concluded with a discussion of the treatment of Graves's disease. [F. J. K.]

3.—This article on the surgical treatment of chronic ulcer of the stomach will be found at length in the *Philadelphia Medical Journal* of May 25th. [J. H. G.]

4.—Martindale maintains that brominol, a compound of bromine and sesame oil, containing 33½% of the halogen in chemical combination, deserves a more extensive trial. He believes that on account of the close combination of

the bromine atoms in the molecules of the fatty acids there is a remarkable stability of the compound brominol. The effort necessary to separate and absorb the bromine from this compound is probably advantageous to the economy. It may be argued that brominol possesses advantages over the potassium bromide on account of its more stable chemical combination. On account of the great chemical solubility of the alkaline bromide, it is absorbed and passes off rapidly without inducing its full action. In a comparative table the author gives the results of analysis of stools and urine from epileptic patients who were under treatment with brominol, and others with potassium bromide.

5.—Payne discusses the value of cacodylate of soda in the treatment of two cases of carcinoma. The first case was that of a woman, 45 years of age, who consulted the author on January 14, 1900, and complained of irregular and profuse hemorrhages from the vagina. On October 5th the patient had a severe hemorrhage from the vagina. The examination at this time revealed ulceration of the cervix and fixation of the uterus. The morbid process was so extensive that operative interference was deemed unwise. On December 16th cacodylate of soda was used hypodermically. The first dose was 2 centigrams. On January 16th, 1901, the dose had been increased up to 7.5 centigrams. The patient refused to continue the treatment on March 14th. The patient's general health had improved, she had gained in weight, and the vaginal hemorrhages had ceased. The patient declared that she had never had cancer and for that reason she gave up the treatment. The second case the author reports occurred in a man 70 years of age, who first came under his observation on August 2, 1900, complaining of a sore mouth and tongue. On examination the tongue was found to be ulcerated. The diagnosis of carcinoma was made on March 17th hypodermic injections of cacodylate of soda were begun. After six weeks of this treatment the author is convinced that the local trouble improved. The author maintains that cacodylate of soda is a valuable palliative remedy in the treatment of cancer, and that this drug should at least be given a trial in inoperable cases. [F. J. K.]

6.—Cautley writes upon acute colitis in children and gives a report of a limited outbreak which came under his observation. All of the cases occurred in certain London barracks. In this dwelling the epidemic began on the third floor, then spread to the ground floor, and then to the first floor. After a most careful investigation the author was unable to ascertain the source of infection. He gives a short account of four cases. Case 1: On June 28th, 1900, a girl, 5 years of age, was admitted into the Belgrave Hospital for Children, complaining of vomiting and diarrhea. Her temperature was normal and the pulse 140. The patient did not complain of pain. The child rapidly grew weaker and died on July 1st. Case 2: This patient, a boy 3 years of age, was admitted to the Hospital on July 1st, complaining of vomiting, diarrhea, and abdominal pain. Fever continued throughout his illness, and the patient died on July 8th. Case 3: On July 18th a female infant, 2 years of age, was admitted into the Hospital suffering from diarrhea and vomiting, and the temperature was 101° F. The diarrhea continued for some time, the child gradually improved and recovered. Case 4: On August 11th, a male child, 3 years of age, was admitted into the Hospital also complaining of diarrhea and vomiting. The temperature was 100° F. and the pulse rate was 130. This patient gradually improved and was discharged recovered on September 17, 1900. Upon postmortem examination in the first case it was found that the entire large intestine was thickened, affecting especially the mucous membrane. Superficial ulcerations were present and small hemorrhages were found in the coats of the bowel. Acute inflammation also involved the last few inches of the ileum, and the mesenteric glands were enlarged. The postmortem examination in the second case presented similar anatomical

lesions. The author concludes the article with a discussion on the nomenclature, suggesting the term "acute catarrhal colitis" for this disease, and a general description of the condition, outlining its course, symptomatology, and treatment. [F. J. K.]

2.—Lund reports a case of perforating gastric ulcer for which he operated 16 hours after the symptoms of perforation appeared. A general peritonitis of such marked degree was present at the time of operation that it was necessary to drain both flanks through the wound in the epigastrium and the pelvis by a second incision, which was made below the umbilicus and through which a tube and gauze were passed. The patient was in perfect health and had normal digestion for a year and 8 months following the operation. Then he was overcome by gas while working in a manhole, but was rescued and resuscitated. An attack of vomiting ensued later, and on the same day he was seized with agonizing abdominal pain. On the fourth day after the attack he was operated upon for acute intestinal obstruction by a band. On opening the abdomen the stomach was found to be normal in size and entirely healthy in appearance. The pylorus was adherent to the under surface of the liver by firm adhesion. The bands that caused the obstruction ran from below the pelvic incision to the jejunum, which at the point of attachment of the second band was sharply kinked and completely obstructed. When, in the course of the operation the intestinal tension was relieved, the patient began to vomit large quantities of feces. He stopped vomiting at about 6 o'clock on the night of the operation; his bowels moved the next morning, and he passed a very satisfactory convalescence. There can be no question that the mortality of the cases operated upon promptly, that is within 12 or 34 hours of the perforation, is and will be remarkably low. The importance of such early operation cannot but be obvious on comparing perforating ulcer of the stomach with appendicitis. The author also referred to a case of a single girl, aged 17 years, who was suffering from chlorosis and who had symptoms of gastric ulcer. She was operated on 10 hours after the onset of the pain which probably signalized perforation. After the operation the young woman had no serious symptoms except a left femoral phlebitis and she left the hospital in 5 weeks. There was a history of gradual aggravation of the symptoms of ulcer during the week preceding perforation, that probably coincided with a gradual increase in the depth and extent of the ulcer, and possibly with the formation of light fibrin deposits upon the peritoneum covering it. These symptoms were sufficiently marked, it would seem, in case they had been observed by a physician to suggest a "preperforative stage." It is fortunate for the surgeon that, although a vastly larger number of ulcers of the stomach are situated upon the posterior than the anterior wall, perforation of the ulcers of the anterior wall is much more frequent than those of the posterior. This fact is undoubtedly due to the greater fixedness of the posterior wall, more frequent affording opportunity for the formation of adhesion that prevent perforation. In case of chronic or intractable ulcer of the stomach, when the situation of the ulcer and the condition of the patient permit it, the surgeon may excise the ulcer and suture the defect in the stomach, thus getting rid of the diseased tissue and affording the most favorable conditions for healing. In cases in which the ulcer is situated near the pylorus, excision of the ulcer may be combined with pyloroplasty, thus relieving the constant irritating spasm of the pylorus, which does so much to keep the ulcer in an active state. If on account of the situation of the ulcer or the condition of the patient excision is difficult, gastro-enterostomy may insure a free passage of the stomach contents into the intestines with the minimum of work on the part of the stomach wall and the maximum of rest, therefore, for the ulcerated surface and the surrounding infiltrated tissue. During the first attack of severe hemorrhage operation is contraindicated, and it would seem that treatment should be limited to rest, opium and salt infusion, as in.

hemorrhage elsewhere. When, however, a first copious hemorrhage is followed by a second, too long delay is hazardous. In spite of the greater complication of the measures required in dealing with a bleeding ulcer of the stomach as compared with a ruptured tube, for example, the use of salt infusion and stimulation, and such measures as prove so successful in intra-abdominal hemorrhage from other causes, will save a certain number of even the most desperate cases from death. The author concludes: (1) That in perforation immediate operation is absolutely indicated. (2) That in cases in which the symptoms fail to yield after medical treatment for a reasonable period, operation, consisting either of excision of the ulcer or gastro-enterostomy, should be performed, and this before the patient has become so exhausted as to render surgical intervention dangerous. (3) That in hemorrhage, were slight, frequently-repeated bleeding promises to produce grave anemia or exhaustion, similar early operation should be done. (4) That in case a patient has suffered from more than one copious hemorrhage, operation should be performed, and the extent and nature of the procedure should be decided upon according to the power of the patient to withstand operative manipulation and the conditions found during the progress of the operation. [J. M. S.]

3.—Abscess of the kidney may be due (1) to injury, (2) to the direct extension of inflammation from contiguous parts, (3) to the extension of inflammation of the pelvis of the kidney through the uriniferous tubules into the substance of the organ and (4) to organisms brought to the kidney by the blood. In the latter cases, except those abscesses that result from the action of the tubercle bacillus, the streptococcus, the staphylococcus pyogenes aureus, the bacterium coli communis, the pneumococcus and the typhoid bacillus are the offending organisms. [J. M. S.]

DEUTSCHE ZEITSCHRIFT FUER NERVENHEIL- KUNDE.

Vol. 18. December 17th, 1900.

The present volume is a *Festschrift* printed in honor of Geheimrath Wilhelm Erb at the completion of his 60th year. It contains 23 articles written by his friends and students.

CONTENTS.

1. The Pathology of Non-Suppurating Encephalitis. Twelve Cases of Encephalitis of the Cerebrum or Cerebellum. Two with Anatomical Investigations. NONNE.
2. Erb's Disease. (Myesthesia. Pseudo-paralytica. Assthenic Bulbar Paralysis.) GIESE and SCHULTZ.
3. The Clinical Characteristics and Pathological Anatomy of Beri Beri. RUMPF and LUCE.
- 4.—Contribution to the Knowledge of Allochiria. DETERMANN.
5. Contribution to the Knowledge of Cerebellar Cysts. SCHUELE.
6. Cases of Hemorrhagic Encephalitis Following Influenza. STADELMANN.
7. Contribution to the Symptomatology of Tumors of the Mid-Brain and the Tegmentum. VON OORDT.
8. The Position of the Fibres in the Pyramidal Tract That Control the Movements of the Hand. HOCHÉ.
9. Casuistic Contribution to the Combined Systemic Degenerations. SCHOENBORN.
10. The Inhibitory Paralysis of Early Childhood (Syphilitic, Rachitic, and other Palsies). VIERORDT.
11. The Relations between Impaired Hearing and Word Deafness. KAST.
12. Thomsen's Disease, with a Special Consideration of the Muscular Atrophies that Occur in it. HOFFMAN.

1.—Nonne gives the histories of 12 exceedingly interesting cases that he diagnoses **encephalitis**. It is difficult to summarize them. In the abstract they are as follows: Case 1. A girl 14 months of age, in the course of an influenza epidemic developed fever, loss of consciousness, vomiting and convulsions, which in a late stage of the disease were limited to the left side of the body. This side was paretic, the reflexes were exaggerated, and there was no disturbance of the eyes. Complete recovery ensued. Case 2. A woman of 34, had an attack of fever, on the 3d day of which she became delirious, had headache, paresis of the left facial nerve followed by paresis of the left side with exaggeration of the knee-jerks. The Widal reaction was negative. As the fever disappeared the paresis improved and the patient recovered completely. An epidemic of influenza prevailed at the time of the attack. Both cases Nonne regards as encephalitis due to influenza. Case 3. A man of 23, became confused, was brought to the hospital, where he developed fever, followed by right facial paresis, sluggish pupillary reaction, some trismus, and on the 5th day an attack of focal epilepsy beginning in the neck muscles on the right side. There was complete aphasia. On the 7th day the fever dropped, and the patient apparently recovered completely with the exception of the aphasia. On the 9th day the patient was capable of recognizing objects, could not understand words, there was complete paraphasia and paragrammatism. On the 12th day he began to be able to repeat words, and two weeks later could understand words perfectly, and exhibited only a slight degree of paraphasia. All forms of infection or intoxication could apparently be excluded in this case, and Nonne suspects that it is possibly a form of hemorrhagic encephalitis. Case 4. A man of 24, had a severe attack of headache followed by confusion, diffuse tenderness of the skull, gradually developing stupor and slow pulse. There was hyperemia of the retina and inequality of the pupils. The reflexes were greatly increased, especially on the right side, and there was ankle clonus. Later the patient improved, and with the exception of a slight disturbance of equilibrium and occasional vertigo, recovered completely. As it seemed possible to exclude brain tumor and serous meningitis, encephalitis was the only condition that could explain the symptoms. Case 5. A man of 28, after a severe journey, appeared much exhausted, then suddenly developed fever, headache, and vomiting. He was delirious

tion, suppurative had irregularity of the pulse and Cheyn-Stokes respiration. Lumbar puncture was negative. Later he had transient nystagnus, strabismus, mydriasis, trismus, and developed a pleural effusion. In the 4th week his symptoms rapidly disappeared, with the exception of a slight sluggish reaction to light in the left pupil. As in the other cases meningitis was apparently to be excluded and encephalitis is the only possible diagnosis. Case 6. A boy of 14, developed a severe headache with vomiting, became confused, delirious, comatose, had severe coric movements, and on the second day, paresis of the left leg, with loss of tendon reflexes. Lumbar puncture was negative. On the 4th day the coma was complete, the whole left side was paretic, and there was marked stiffness in the muscles of the neck. Later there was cutaneous hyperesthesia, but consciousness returned and the patient complained of a severe headache in the back of the head. At the end of the 4th week there was slight atrophy of both optic nerves, occasional vomiting, tenderness of the skull and headache. At the end of 11 weeks the patient was discharged, but even up to that time there were occasional attacks of headache and vomiting. In these cases the diagnosis was encephalitis associated with basal meningitis due to the same cause. Case 7. A man of 45, was exposed to cold and had an attack of fever followed by headache and vomiting. In the course of 4 days the only nervous symptom was diminution of the muscle tone. He later developed a typical cerebellar gait. There was exaggeration of the tendon reflexes, but at the end of a week the condition improved considerably and the patient ultimately recovered completely. This is probably a case of encephalitis in the cerebellum. Case 8. A man of 28, had for three months been rapidly emaciating. He developed severe headache with vomiting, inability to stand, and was quite delirious. From time to time there were clonic contractions in the legs; the gait was typically cerebellar in type; there was diminution in power. There was ankle clonus on the right side, and slight nystagnus, but the patient gradually recovered, and, with the exception of a permanent exaggeration of the reflexes, seemed perfectly well. This is also probably a case of cerebellar encephalitis. Case 9 was very interesting, showing briefly the following changes: After acute cerebral symptoms in the 11th year of age there developed incoordination of motion and of speech, insufficiency of the external muscles of the eye, impairment of intelligence, active tendon reflexes, but no disturbance of sensation nor of the action of the sphincters. Case 10. A man of 29, 15 months after sunstroke, showed the following changes. Incoordination of the extremities and speech, although mimicry was not disturbed. Insufficiency of the eye muscles, exaggeration of the tendon reflexes, hyper-tonicity of the muscles, but no disturbance of the action of the sphincters. These symptoms persisted unchanged for 4 years. These 2 cases present great difficulties in diagnosis. Multiple sclerosis and spinal disease seem to be excluded, and Nonne therefore includes them in the group of forms of encephalitis. Case 11 had inflammation of the throat, then weakness of the muscles of the neck, intelligence was undisturbed, respiration was very rapid. There was considerable pain if the head were forcibly bent backward. The left arm became paralyzed, then the face. The patient developed nystagnus, and finally there was paresis of the left leg. The reflexes remained normal. At the autopsy nothing was found either macroscopically or microscopically that could be considered pathological, and the case therefore is sufficient proof of the fact, hitherto not recognized, that encephalitis may exist, and even lead to death, without producing any recognizable changes. Case 12. A woman of 38 had felt depressed for several weeks, then developed weakness in the left leg. There was headache, nausea, and clonic contractions in the left side of the face. There was stiffness in the neck, diverging strabismus, and mydriasis of the left pupil, and total loss of pupillary reaction. Lumbar puncture gave a hemorrhagic fluid under considerable pressure, although no bacteria were found in it. The patient developed convulsions, the left hemiplegia became complete, and death occurred as the result of increase in the temperature. At the autopsy there were found numerous grayish-yellow nodules in the central convolutions and brownish discoloration of the brainy substance on the left side, from the frontal to the parietal regions. Microscopically there was inflammation and

infiltration of the pia, and round cell infiltration of the brain substance. The walls of the arteries and capillaries were infiltrated with round cells, and many of them were obstructed. Tuberculosis of the pleura and lungs existed, and Nonne considers this a form of encephalitis due to the poison of this microorganism. [J. S.]

2.—The following is reported as a case of Erb's disease. A woman, 24, with negative family history, had an attack of coryza and bronchitis associated with severe pain in the right side of the head. A few days later there was diplopia, then difficulty in swallowing with regurgitation of fluids through the nose. Shortly after this there was difficulty in speaking, fatigue after chewing, and later ptosis, transient paralysis of some of the fingers after use, and general fatigue after any kind of exertion. Intelligence and sensation were not affected. When examined 4 months later there was ptosis on the right side, the right internal rectus was completely paralyzed; there was paralysis of the soft palate and paresis of the tongue. All the muscles were well developed; there was no fibrillary twitching, but there was distinct paresis, and fatigue occurred very rapidly. The tendon reflexes were present, but not abnormal. There were no reactions of degeneration in the muscles, but an imperfect myasthenic reaction was present. The voice showed partial aphonia, otherwise everything was negative. The patient showed slight improvement, although fatigue occurred so rapidly that when the lips were exposed, the upper lip would sink from exhaustion at the end of a minute. Subsequently the patient became again somewhat worse: the tendon reflexes were diminished, but the patient left the hospital. From these symptoms a diagnosis of asthenic muscular paralysis was made. Subsequently the aphonia became complete, and the patient developed dyspnea, increased rapidity of the pulse rate, and finally died. The autopsy was absolutely negative, both microscopically and macroscopically, thus confirming the diagnosis. Schultz, in some concluding remarks, approves the name "Erb's disease" because we know so little about the true pathology of the condition that a more accurate designation is not at present possible. He believes, however, that it represents some form of intoxication, and calls attention to the presence of cystinuria as a proof that intestinal putrefaction was probably present, although the earlier symptoms recall those of diphtheria, and diphtheritic paralysis might have been suspected; the later course of the disease was sufficient to exclude this complication. [J. S.]

3.—Rumpf and Luce have had the opportunity of studying 10 cases of *beri beri*, which occurred in sailors, chiefly Chinese, arriving from the Orient. Nine recovered and one died. The symptoms were those ordinarily described, that is, slight disturbance of sensation, paresis or paralysis in the limbs, disappearance of the tendon reflexes, and qualitative or quantitative disturbances in the electrical reactions of the muscles. It is perhaps of interest to note that 6 of the patients were Chinese stokers. Microscopically, changes were found in the peripheral nerves with fatty infiltration of the connective tissue and moderate reduction of the myeline sheaves. In the spinal cord there was a recent degeneration of the myeline sheathes, local areas of degeneration, and a very slight degeneration in the cells of the anterior cornua. There was a chronic interstitial neuritis involving the posterior roots. This confirmed the findings of the other investigators. They therefore concluded that the disease represented the action of some inflammation upon the peripheral nervous system. All the cases showed the anemic type; the symptoms corresponded to those of polyneuritis, complicated in all probability by some changes in the muscle substance itself. A curious feature is that in none of these, nor in the majority of recorded cases, was the paralysis absolute in any of the muscles. It is probable that in the hydropic form there is serious disturbance of the kidneys. [J. S.]

4.—Deternann reports the following interesting case: The patient, who had had luetic infection, had diplopia, slight feeling of numbness in the hands, and slight difficulty in their use. The tendon reflexes were abolished; all forms of sensation were diminished in the hands; the stereognostic sense was diminished; the muscular power was fairly good. When the patient was stuck with a pin in the right hand there was a similar sense of contact about two seconds later, if slightly larger in area, in the left hand. The case represents one of locomotor ataxia affecting chief-

ly the cervical region, presenting the interesting features of *allochiria*. The case represents the 2 types of reflex and sensory *allochiria*, and is interesting because the patient had in the left hand the sense of burning pain and contact, moreover because the sensations commenced gradually, although the irritant in the right hand was applied only for a moment. Determann believes that the theory, that sensation is shifted in the spinal cord to the wrong tract, so that it is conveyed to the hemisphere on the same side and produces the sense of pain in the opposite side of the body, applies to the majority of cases, but not to those in which the symptoms are purely hysterical. [J. S.]

5.—Schüle reports the case of a man 39 years of age, an alcoholic. He had a severe fall, striking the back of his head, and after this complained of headache. There was loss of memory, attacks of vertigo, frequent vomiting and loss of weight. There was slight venous hyperemia of the eye-brows, but otherwise all the ocular phenomena were normal. There were no tremors, but slight ataxia in the upper extremities. From time to time there were attacks in which the patient seemed confused and groaned loudly, and appeared to be extremely restless, but no true convulsions occurred. Death occurred about 7 weeks after the injury. A diagnosis was made of tumor of the cerebellum, particularly on account of a tendency to fall backward. At the autopsy the skull was found perfectly normal, and the cerebellum appeared normal, but was slightly elastic, and upon a median incision a large cyst was found in the vermiciform process lined by a smooth wall, and about 3.5 by 4.5 cm.. The floor of the cyst formed the roof of the 4th ventricle. In all likelihood there was in this case a congenital diverticulum into which as a result of the injury there was a sudden effusion of liquid, causing the symptoms. Only a single similar case is to be found in the literature. [J. S.]

6.—Stadelmann reports the case of a man 28 years of age who had had an attack of influenza that had commenced with headache, fever, and vomiting. This lasted about 8 days and then was replaced by pain in the back. When admitted to the hospital there was moderate fever, inability to bend the head forward and backward, although it could readily be bent from side to side, some stiffness in the back of the neck, and tenderness over the 10th to the 12th dorsal vertebrae. A diagnosis of neuralgia following influenza was made, and the patient improved upon treatment. On the 10th day, however, he had a relapse, and appeared as if about to die. The temperature rose, then fell suddenly, and the patient had remittent fever with increasing apathy, bitter complaints of headache, right hemiplegia, with anesthesia and finally death. 10 days after the collapse. Spinal puncture had shown the existence of a reddish fluid. At the autopsy there was found chronic spinal meningitis, hemorrhages into the brain, hemorrhagic and anemic softening in the left hemisphere, hematoma of the left lateral ventricle, and of the subarachnoid space. Stadelmann regards the case as one of *cerebral softening following influenza* and producing hemorrhage. [J. S.]

7.—Van Oordt reports the following case: The patient, a girl, 8½ years of age, had developed slight weakness of the muscles of the right side of the face, bilateral ptosis and disturbance of gait. When admitted to the hospital it was found that the speech was slow and scanning, the eyes were normal; there was no disturbance of the other muscles excepting slight paresis of the superior and inferior recti on the right side, and possibly of the external rectus. There was also slight paralysis of the lower branch of the facial nerve on the right side. There was no paresis of the extremities, but a marked extension of tremor, and ataxia of both arms, more pronounced on the left side. Occasionally there were athetoid and choreitoid movements of the hands. There was considerable staggering during walking. There was alimentary glycosuria, and subsequently some evidence of diabetes. This improved rapidly upon suitable diet. About 3 months after the first symptoms the patient had violent vomiting, clonic convulsions in the right arm and died. There was a *tubercle of the tegmentum* about the size of a nut that obliterated the aqueduct of Sylvius and destroyed the right portion of this area, the right posterior longitudinal tract of fibres, and the right lateral nucleus of the fillet; it partially destroyed the right posterior corpus quadrigeminum and a considerable portion of the left posterior quadrigeminum, and the nucleus of the oculomotorius. There was some compression of the structures on the left side. Van Oordt also re-

ports the presence of a nucleus between the fibres of the restiform body near the mesial border of this structure consisting of from 25 to 40 round, pear-shaped ganglion cells similar to those of the olive. The right olivary body was degenerated, but this nucleus remained intact, and its cells differed slightly in size from those of the normal olive. Van Oordt regards it as a normal structure. After a brief description of the secondary degenerations he discusses the diagnosis from the symptoms. In view of the paresis of the right eye and of the left half of the body the localization of the tumor was made quite readily. The hypalgesia of the left side can be explained by the lesion of the tegmentum; the ataxia, by the involvement of the corpora quadrigemina and the tracts to the cerebellum. The patient had complete control of the stereognostic sense, probably due to the fact that the median fillet was nearly intact on both sides. There was no diminution in the visual activity, and there were no symptoms of brain compression until the convulsions just before death. It was doubtful whether the glycosuria was due to the tumor, but Van Oordt has collected 31 cases, in which this symptom appeared, 18 of these involved the floor of the 4th ventricle, and some the pons and the corpora quadrigemina. [J. S.]

8.—Hoche reports the case of a woman, 54 years of age, in whom the symptoms commenced with a typical attack of epilepsy, which was subsequently followed by attacks of twitching and paresthesia of the left arm. There was no vomiting, but slow development of weakness in the left hand. An operation was accordingly performed and a small tumor found in the *ascending frontal gyrus* about the level of the superior sulcus, which extended more than 1.5 cm. into the brain substance, and was not sharply delimited. It was found to be a spindle-cell sarcoma. The patient gradually grew worse; the paralysis of the left side extended, and finally death occurred. An interesting feature is that the typical cortical convulsions persisted after the operation. The degenerated fibres traced from this area formed, in the crus, a triangular area about the centre. In the pons, the whole pyramidal area contained degenerated fibres. This was also true of the pyramidal tracts in the cervical cord. The interesting feature of this case is that such a functionally distinct group of fibres as those supplying the hand, are not collected into an individual bundle at any point below the crus. [J. S.]

9.—Schoenborn reports two interesting cases. A boy of 13, the son of nearly related parents, with 4 healthy brothers, and one who suffered from the same disease, at the age of 13 noticed some twitching in the knees. This was followed by some uncertainty in gait and the legs seemed weak. The ataxia was more pronounced in the dark, and there was scanning speech. The patient had bilateral ptosis, moderate nystagmus, no muscular atrophies, some hyper-extension of the fingers and toes, no disturbance of sensation, moderate diminution of the tendon reflexes, slight lateral deviation of the spinal column. There was no defect of intelligence. The 2nd patient, a brother of the one just described, now 27 years of age, developed the first symptoms at the age of 25. These were essentially the same as those of his younger brother. Atrophy in the legs, some pains, slight tremor of the arms, scanning speech, and static ataxia without disturbance of sensation or atrophy of the muscles. The reflexes were much exaggerated on both sides, and Babinski's reflex was present. Regarding the nature of this condition Schoenborn is inclined to believe that it is really a form of combined sclerosis of the cord, although many of the symptoms resemble those of Friedrich's ataxia, or cerebellar ataxia. Many other symptoms and characteristics of the disease failed to agree with these two conditions, particularly the exaggeration of the reflexes, and the late onset of the second case. [J. S.]

10.—Vierordt discusses the *pseudo-paralyses of children*. He criticises Parrot's idea that in these cases syphilitic and rachitic disease of the bone is sufficient to explain the paralytic symptoms. He reports 2 cases which were characterized by paralysis of the lower extremities, coming on at the age of 1½ and 2 years. In the latter case the child was able to stand before the disease developed. The limbs were not especially tender; the spinal column was excessively mobile; there were no signs of syphilis, but modern rachitis in both. The paralysis was flaccid, but there were no reactions of degeneration. Both recov-

ered completely. Vierordt regards the paralysis as the result of loss of power, and the hypertonicity of the muscles. He excludes the possibility of Chassaignac's disease on account of the absence of pain. He also calls attention to a condition of paralysis of the muscles of deglutition that occurs in children who have been subjected to tracheotomy. He has observed it in 70% of the children under 2½ years that have had this operation performed upon them in his clinic. It usually persists during the period that the canula is in position. In conclusion he states that in young children paralysis may occur as the result of peripheral irritation, especially of the skeleton, and that therefore we are justified in assuming the existence of a pure functional paralysis, the result of irritation of the inhibitory centres, and that this paralysis disappears as soon as the peripheral irritation discontinues. [J. S.]

11.—The following case is interesting because there is reason to believe that as a result of a peripheral affection of hearing the patient developed a certain degree of word-deafness. He was a man 34 years of age, who in pursuance of his occupation of letter-carrier in the country, was exposed to severe weather. He had 2 attacks of pneumonia, both of which were associated with severe cerebral symptoms. Convalescence was slow. He then developed weakness of memory, ataxia, severe headache, and gradually impaired hearing in the right ear that soon reached complete deafness. The same thing occurred a short time later in the left ear, after which there was moderate improvement. It became impossible to communicate with the patient except by writing, nevertheless, careful observation showed that he perceived sounds, and testing proved that the watch could be heard at a distance of 60 cm. on the left, and 30 cm. on the right side. He could hear distinctly all musical notes, but in his attempts to reproduce them always struck an octave higher. When words were spoken he perceived only an indistinguishable sound. He was unable to repeat any of the vowels, could not understand any of the consonants, but realized that there was more of a blowing tone in "P" and "V" than in the others. He was unable to recognize tunes, but if started in singing one that was familiar, could carry it through very well. He could recognize the quality of voices so that when a person spoke that he could not see, he could state who it was. He was also capable of distinguishing whether the sound was made by striking wood, metal or glass. He had distinct ataxia increased by closing the eyes. As a result of careful treatment considerable improvement took place in his hearing, and he was able to make an attempt to imitate words that were spoken to him. The ataxia, however, increased, and later the deafness was stationary. Kast reports the case as probably due to meningitis following pneumonia with involvement of the labyrinth, and probably a functional word deafness. [J. S.]

12.—Hoffmann reports 2 cases of myotonia congenita in a brother and sister. The first, a man of 26, first noticed the symptoms at the age of 22, after 3 years service in the cavalry during which he was exposed to very cold weather. He noticed that his hands became very much weaker, that his face and arms got thinner, that it was difficult for him to speak in the morning, and that cold greatly increased his weakness. The muscles showed some quantitative diminution of electric excitability and distinct myotonic symptoms. These symptoms were present only in the muscles of the face and arms. A sister, 32 years of age, had had rheumatism at the age of 24, but believed herself to be perfectly healthy. There was atrophy of the muscles of the face and fore-arms and hands, distinct myotonic reactions in these muscles and in those of the lower extremities. The common characteristics of the 2 cases, therefore, were the myotonia and the atrophy of the muscles in the upper extremities and sterno cleido mastoid. Hoffmann has carefully studied the literature, and has been able to collect 5 cases in which myotonia was associated with muscular atrophy, and 3 cases in which there was reason to believe that the loss was in part a feature of the disease. He suggests 3 possible hypotheses. First, that the 2 conditions accidentally occurred in the same individual, that there is progressive muscular atrophy with myotonia, or that there is myotonia as a result of which muscular atrophy occurs. He does not decide which of these is correct, although he believes in his own case that the combination is not accidental. He calls attention to some other interesting cases in which the myotonia occurred suddenly, apparently as a result of excessive exertion. In conclusion he

mentions the case of a man 42 years of age, with luetic history, whose organs were apparently normal, the pupils reacted well, but there was disappearance of the patella reflex, some paresthesia in the extremities and difficulty in walking in the dark. There was a distinct myotonic reaction to percussion. Hoffman makes a diagnosis of myotonia with beginning locomotor ataxia. [J. S.]

(To be Continued.)

1.—Bier has performed a series of most interesting experiments by the **transfusion of blood** from an animal of one species to one of another. Starting out with the idea that the animal organism can accustom itself to very varied conditions, he attempted to accustom rabbits to injections of lamb's blood. At first the animals appeared to agree with the theory, and then, as the dose of blood was increased, they suddenly died with all the manifestations of transfusion collapse. The autopsies showed capillary congestion of the intestines, spleen, liver, lungs, kidneys, etc. The symptoms of transfusion are dyspnea, with bloody expectoration, flushing, subjective heat of the skin, pain in the back, and increased peristalsis. Usually there is also some fever. It is possible that the increase in the symptoms is due to the fact that the blood of the receiving animal gradually acquires increased hemolytic qualities, and may, in the end, dissolve its own corpuscles. Nevertheless, as by transfusion it is possible to combat severe anemias, or to bring about conditions of hyperemia Bier undertook a series of clinical experiments. These were performed in the following manner. Blood was obtained from a lamb and carefully defibrinated under aseptic precautions, then a needle was thrust into a distended vein at the bend of the elbow, the pressure above removed, and injection commenced. As a rule a syringe holding 50 cc. was employed, and the injection continued until slight symptoms of transfusion appeared. It was found that at first larger and larger quantities could be used, then suddenly only very small quantities. He reports in great detail the case of a man 22 years of age who had severe tuberculosis of both sacro-iliac synchondroses, which had suppurred and broken through the skin at numerous places. He was given ascending doses of lamb's blood until 10 ccm. had been injected. After this it was found that only smaller and smaller doses could be used until finally only 1.5 ccm. could be employed with safety. The general condition of the patient improved remarkably; the suppuration almost entirely ceased; the appetite increased, and the weight im-

proved slightly. The patient was under observation about 2½ months. Further, 10 cases of other forms of tuberculosis, nearly all of them presumably fatal, with the exception of 4 cases of lupus, were under observation. Three of these died, one of starvation on account of the tuberculosis of the esophagus; one of sepsis, the condition existing before the treatment was commenced, and one of tuberculosis of the brain. The others improved, or at least remained stationary. The majority of cases of pulmonary tuberculosis gained considerably in weight. The 4 cases of lupus, all of which had been previously subjected to treatment without results, showed extraordinary improvement. Whether this is permanent or only temporary, remains to be seen. Certain clinical observations were made: First, there was generally flushing of the face; the majority of patients felt a desire to defecate and usually expelled a large stool some time after the injection. Occasionally urticaria appeared. Nearly all the patients developed excessive appetite; most of them had fever and chill without any subjective signs of discomfort, and the majority had a feeling of dryness in the mouth, and very severe thirst. The author believes that the action is due to the following changes. First, temporary hyperemia produced by capillary congestion, giving rise to a serious infiltration of various parts of the body, and probably most severe in the diseased regions. Second, vigorous stimulation of metabolism. Third, an aseptic transfusion fever. Fourth, possible alteration in the quality of the blood. As lamb blood appears to be least toxic for men, it is probably the most available. [J. S.]

2.—Petersen calls attention to the great difference in the statistics of **gun-shot wounds of the abdomen** in civil and military practice. In the first the mortality appears to have decreased, probably chiefly because the patients are seen earlier. In military surgery it seems to be the chief opinion that a conservative treatment gives the best results, but even in civil practice there is much diversity of opinion regarding the necessity of immediate operation. He reports a number of cases. Eight were operated upon as soon as possible, of whom 3 died and 5 recovered. Two were not operated upon. One of these died of diffuse peritonitis; the other recovered. However, the results showed that in all cases in which operation was performed it was imperatively necessary. In regard to the indications for operation, he believes that the *absence of liver dullness* is of less significance than is usually believed. The *disappearance of liver dullness* is however, of more value. The most important symptoms were tension of the abdominal muscles, local meteorisms, and dullness in the region of the wound. The general symptoms were those of peritonitis. He concludes that the treatment should not be influenced by the statistics of military surgeons, but that in all cases in which there is a suspicion of perforation, operation should be performed at once. As delay in operation is more serious than an exploratory incision, the latter is always indicated. Expectant treatment should never be employed unless the patient can remain under constant supervision. [J. S.]

3.—The result of the war in South Africa in regard to **wounds produced by bullets of small calibre**, are exceedingly interesting. Simple perforative wounds of the soft parts usually heal in the course of from 14 to 18 days, without further disturbance. Occasionally if the muzzle of the gun was close to the flesh at the time of discharge there is superficial necrosis. In cases where there is hemorrhage into the cavities of the body the prognosis is rather less favorable. It does not appear that nerve trunks are often divided. Injuries to the diaphyses of the bones often causes splintering; those to the epiphyses, sometimes simple perforation. The joint is, however, often involved in the latter case. The prognosis in these, as in all other injuries, is favorable provided infection does not occur. However, it is an interesting fact that vigorous disinfection of the wound does more harm than good. Sthamer has been in the habit of cleaning the surrounding skin sufficiently

to fix an occlusive dressing, and of avoiding any contact with the opening of the wound. The object of this treatment is of course to admit the development of clots and thus prevent the entrance of an infectious element. It is not even necessary to have the bandage antiseptic. On the other hand it must be dry and capable of absorption. He reports some remarkable cases. One soldier was shot through the region of the stomach. He then rode 3000 meters and was obliged to remain overnight in the camp and only on the following day he was transported to the hospital. There was no fever; the pulse was strong and slow. Death however, occurred suddenly as a result of bleeding from a small vessel in the mesentery. The colon and stomach had been perforated, but there were no signs of peritonitis. In another case the patient was shot through the stomach and kidney; there was blood in the urine, but no other symptoms and recovery ensued. [J. S.]

4.—Discussing the theories of **multiplicity of primary malignant tumors**, Nehr Korn calls attention to the great importance of multiple carcinoma of the skin, which may be due either to some chronic irritation or multiple implantation. He reports 3 cases; the first, in which 2 small carcinomas appeared upon the left temple of an old man; the 2d in a man of 52 when 3 small carcinomas were found also in the skin of the head; and the 3d, an old woman with tumor of the ear and upper lip; the former a squamous epithelium, the other an adenoid carcinoma. The reason why skin carcinomas are more frequently multiple than intestinal carcinomas that are also exposed to multiple implantation, is that the latter more readily escape observation and as the primary growth develops more rapidly, the other foci do not have time to appear. Simultaneous involvement of symmetrical glands is relatively uncommon for the breast and quite common for the ovaries. Tumors may also occur simultaneously in different parts of the body. He reports the case of a woman 58 years of age who had carcinoma of the breast and uterus at the same time. Another patient, a man of 62 who had a carcinoma of the bladder, and subsequently one of the rectum. Of a man of 62 who had an epithelial tumor in the pharynx, and another at the side of the tongue, and finally, a woman who had a melanotic sarcoma with multiple metastases, and carcinoma of the uterus. In conclusion he laments the unsatisfactory state of our theories upon this subject. [J. S.]

5.—Heinz has performed a series of studies upon the pleural cavity in order to determine certain facts regarding caustic action. Having failed with turpentine suspended in water to produce a reaction he employed the aleuronat suspended in water, and was able to produce a typical inflammation, but not a pure leukocytosis. On the second day he found in the exudate in addition to the white and red blood corpuscles, fibrin and plasma, a number of large mononuclear cells evidently from the endothelial surface. When these were examined under a microscope placed in a thermostat he found that they exhibited very active amoeboid movements. This merely proves that they have the same qualities as the endothelium lining the blood vessels. [J. S.]

6.—The first case, a woman 41 years of age, had symptoms of mitral stenosis. While under observation she suddenly developed cramp-like pains in both legs, then pallor and cold, with loss of sensibility and active movements. These symptoms rapidly extended upward, and were associated with extreme pains in the limbs. Gangrene appeared, the pulse in the ural artery was lost. At the amputation of both legs, it was found that the crural arteries were thrombosed. The patient died, and at the autopsy embolism and thrombosis of the abdominal aorta was discovered. The 2d patient also had the symptoms of mitral stenosis during which he developed severe pains in the legs, with loss of power and sensation, coldness and absence of pulse in the crural arteries. Gangrene occurred and there were symptoms of peritonitis. The patient had albumin and casts in the urine. At the autopsy there was embolism of the left artery of the Sylvian fossa and abdominal aorta, and numerous infarcts in the spleen and kidneys. These cases are interesting because they indi-

cate very clearly the etiology of the lesion, that is, the mitral stenosis. In one case the thrombus of the heart was probably dislodged by the medication with digitalis. The symptoms of embolism of the aorta are variable, according to the extent and location of the obstruction of the aorta; but in general they consist of cold and pallor, then livid discoloration of the skin of the limbs, loss of sensation, motion, and pulse, and finally gangrene. It is interesting to note that in one case the stethoscope placed over the crural artery transmitted a dull tone that evidently came from the aorta. Both cases showed intense pain in the limbs throughout the course. In the second case the abdominal symptoms were due to occlusion of the mesenteric artery. The prognosis of this condition is fatal, and the treatment of course, unavailing. [J. S.]

7.—Fromme has endeavored to determine the value of glutoid capsules for the diagnosis of gastric motility. He found that there is considerable difference in the time in which the reaction with iodine occurs, and concludes that if it appears between $3\frac{1}{2}$ and 5 hours it indicates good gastric motility and good pancreatic function. If it appears later than 7 or 8 hours this may be due to various causes. It may be retained in the stomach, or it may have become dissolved in the stomach, for there is no way of proving that the capsule itself is still present in that organ. [J. S.]

8.—Muehlig reports 2 cases in which as the result of extensive burns upon the arm bismuth dressings were applied causing bluish discoloration, swelling and superficial ulcers of the gums. These were only controlled when the bismuth still adhering to the granulations was removed.

9.—Schueltz reports the case of a man 62 years of age, who after an attack of influenza, had difficulty of deglutition, with a sensation of obstruction just above the stomach. The passage of a no. 22 sound was without result. The stomach contents contained no free HCl, but there was some lactic acid. Microscopical examination showed masses of squamous epithelium and some blood. A soft stomach tube was therefore passed every day and partial faradism applied to the esophagus. The patient was soon able to swallow without difficulty and recovered his health entirely. After excluding ulcer and carcinoma, Schueltz attempts to make a differential diagnosis of atony of the esophagus, and esophagitis. He believes that the latter was present partly on account of the discovery of blood, and partly because the condition of the stomach predisposed to this affection. [J. S.]

10.—Langer reports the case of a child 18 months old who swallowed a considerable amount of soft soap. Treatment was unavailing and the child died the same night. At the autopsy changes were found in the gastro-intestinal tract that indicated the presence of some caustic substance, and at the same time the presence of an inflammation of the lung. It was not certain whether the poison was sufficient to cause this inflammation, but the latter was evidently the immediate cause of death. The amount of potassium or sodium hydrate in soft soap from 8.5 to 12%. Administered to 2 dogs through an esophageal sound it caused vomiting in a short time. Both animals however, recovered in the course of 4 or 5 days. In one dog that was killed there was some irritation at the cardiac end and along the lesser curvature. The results prove the great danger of many common substances to children. [J. S.]

11.—Spiess highly recommends orthoform for whooping-cough. In order to combat the local alteration in the mucous membranes of the pharynx he insufflates 2 or 3 times every 2 hours, and in small children 3 or 4 times in the course of a day. It causes no discomfort and apparently relieves the attacks. [J. S.]

12.—Karehnke reports the case of a man 72 years of age, who in attempting to bite a crust of bread, dislocated the left maxillary articulation, but it was replaced without difficulty. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

March 21, 1901. (XIV Jahrgang, No. 12.)

1. Mushroom Poisoning. HUGO GOLDMAN.
2. Affections of the Joints in Scarlet Fever. EDMUND HOMA.
3. The Primitive Organs of Sight. THEODOR BEER.

1.—Last summer Goldman treated 11 cases of poisoning following the ingestion of the agaricus torminosus. The first cases were three children from 2 to 14 years of age, who had gathered the mushrooms, cut them up, and eaten them. The youngest one died in spite of all treatment, in 24 hours. Soon afterward, eight Polish laborers, mistaking the agaricus for an edible mushroom, collected and ate them. Out of this number, two women, who had eaten most heartily, died from 5 to 6 days afterward. Still, they only received their first treatment on the third day of illness, while all the rest received immediate attention. The agaricus is very common in the woods about Vienna all summer, it is yellowish white, stands about 4 cm. high, and burns slightly when tasted. It looks much like the 'champignon.' The poison in it is unknown. The symptoms are those ordinarily seen in cholera morbus, coming on about four hours after the mushrooms have been eaten. Goldman found the skin dry and icteric, pupils dilated, tongue deeply coated, and tremulous, very slight fever, abdomen and epigastrium somewhat tender, much vomiting and severe diarrhea. At autopsy, acute gastro-intestinal catarrh and slight fatty degeneration of the liver, kidneys, and heart were found. Goldman's treatment was tannin by mouth and rectum. As prophylaxis, he recommends that the market officials and the people, especially the children, be taught to recognize the poisonous varieties of mushrooms. [M. O.]

2.—Joint inflammation is not uncommon in the infectious diseases. After reviewing the literature, Homa reports 14 cases in which synovitis occurred during scarlet fever. In only one of these was the effusion purulent. He treated 506 cases in five years. The joint affection appears in the first or second week of scarlet fever, about the beginning of desquamation, in severe cases, with pain and some added elevation of temperature. Swelling was only observed in 5 cases. The symptoms generally disappear inside of a week. 6 of the cases had two such attacks, one case three. The wrist was affected 8 times, the elbow 7, knee 5, ankle 4, and the hip and shoulder once each. In 10 of these it occurred on both sides of the body. The treatment was rest, moist dressings, and in four cases only, sodium salicylate. Homa could not find any peculiarly favorable action of the salicylates. The histories of his 14 cases follow in detail. [M. O.]

3.—Will be abstracted when concluded.

March 28, 1901. (XIV Jahrgang, No. 13.)

1. The Pathology and Treatment of Migraine. M. SIHLE.
2. Three Cases of Cataract from Lightning-Stroke. JOSEF PREINDLSBERGER.
3. The Primitive Organs of Sight. THEODOR BEER.

1.—In spite of the frequency of migraine, its origin is still obscure. Sihle calls attention to the fact that the aura, a limited area of paresthesia, hyperesthesia, etc., is generally found upon the opposite side from that upon which the migraine occurs. Sihle reports his own case. He is now 38 years old. His father had lung trouble; his mother much headache, and her brother was epileptic. His brother had migraine and rheumatism. Sihle had pleurisy nine years ago, followed by frequent cough and hemoptysis. It was at this time that he first noticed "gleams of light" or "bright specks" before the eyes. This has often recurred since, succeeded by severe migraine. Tubercle bacilli were found in his sputum 8 years ago. Pleurisy occurred the next year upon the other side, followed by aphonia. For the past 5 years he has been better physically, and fully able to work. He noted that the appearance of these "bright specks" was to one side of the point of fixation, while the headache which followed occurred over the temporal bone of the opposite side, and was very severe. This migraine lasted two hours or longer. These attacks occurred about once a month, growing gradually more seldom. During the past three years he has had none. Of the 10 attacks observed by him in detail, the "light" appeared 7 times to the right, and only three times to the left, so that the pathological change occurred more

often in the left hemisphere. As the pain occurs after the aura, and upon the opposite side, it has probably but secondary significance. Omitting the pain, the position of the probable cause of migraine can be determined. This is a **hemispherical change, probably degenerative**, found not in any one especial place, but in **several parts of the brain cortex**. The degeneration can evidently recover. Tuberculosis, or any other toxic condition can undoubtedly be the exciting cause of the migraine. After a full discussion of the theories advanced to account for the occurrence of migraine, he suggests that the **pain may be due to irritation of the meninges**, secondary to the effect upon the cortex of the toxic cause of the migraine. Intoxication must be the main cause of both epilepsy and migraine, and the headache in migraine and in epilepsy is but the secondary manifestation of the toxin. They are not the same illness, though they have the same causes. Is migraine epilepsy without convulsions, or is epilepsy an advanced stage of migraine? The answers Sihle leaves to the future. [M.O.]

2.—Two of the three cases reported which had been struck by lightning had cataract develop in both eyes, two days afterward. One was a boy of 13, the other 11. Both were unconscious, the elder for a short time only, the younger for two days. He had also been burned. In both cases **linear extraction** was performed, with success. The third case was a man of 24, who had been struck by lightning 6 years before. He was unconscious for 10 minutes only. A cataract developed in the right eye alone, some months later. Preindlsberger performed **extraction with iridectomy** with success. The condition is quite rare. [M.O.]

3.—Beer's article is most modern and complete, yet technical. He uses an entirely new nomenclature. He describes the **primitive organs of sight** in the lowest animals, tracing them up to the higher, from the simple, pigmentless cells, to the pigmented, highly specialized organs of man. He minutely gives means of telling whether an animal is or is not blind. [M.O.]

ARCHIVES DE MEDECINE EXPERIMENTALE.

March, 1901. (13me. Année, No. 2.)

1. A Case of Purpura Simplex. G. CARRIERE.
2. Hemorrhagic Pancreatitis in Typhoid Fever. A. CHAUFFARD and P. RAVAUT.
3. The Action of Typhoid Bacilli on Human Blood. E. MAUREL.
4. Primary Massive Tuberculosis of the Spleen. F. J. COLLET and LOUIS GALLAVARDIN.
5. Arterial Sutures. J. BOUGLE.
6. The Histogenesis of the Tubercle. CHALES MOREL and DALOUS.
7. Carcinomatous Lymphangitis of the Lung. E. TROISIER and M. LETULLE.

1.—Carrière reports a case of **purpura simplex** occurring in a boy of 14. Anorexia has existed for a month, with some emaciation and weakness. There has been slight pain in the knees, ankles, and legs before the eruption appeared. This was almost symmetrically arranged about the joints, with some ecchymoses on one nostril and eyelid, and larger spots on the right scapula and left buttock. There was no fever or edema; though bleeding from the gums occurred. Blood examination showed 17,900 leucocytes to 4,350,000 red corpuscles. 65% of the leucocytes were polynuclear; 15% were eosinophiles; and there were no large lymphocytes. Cultures from the blood with inoculation and experiments gave a **bacillus**, aerobic and anaerobic, similar to that found by Achalmé and Thirlix in acute rheumatism. Carrière, who has also investigated that bacillus, believes that they are identical. It shows remarkable polymorphism, and is probably the same microorganism taken by other observers for staphylococci or diplococci. [M.O.]

2.—The first reported case of hemorrhagic pancreatitis occurring in the course of typhoid fever is described by Chauffard and Ravaut. A man of 40 entered the hospital on the day before his rose-spots came out. Defervescence began on the 19th day. A few days later the temperature rose and a relapse was feared; but in 10 days all symptoms had disappeared. On the 52nd day he had a sudden pain

in the right hypochondrium, in the umbilical line, followed by distension. His pulse shot up to 120-160, and became small and filiform. Fever only appeared two days later. It was supposed that perforation had occurred, yet the symptoms gradually subsided. 66 days later dyspnea appeared with left sided bronchopneumonia, and he died a week later. The pancreas was found surrounded with hemorrhagic cellular tissue. There was no trace of perforation or peritonitis. Both pancreas and lungs showed marked congestion. Perforation generally occurs before the 52d day. Death by syncope 66 days after the pancreatitis was perhaps brought about by the sympathetic nerve plexus. Examination of the pancreas shows the absence of fatty degeneration; evident venous stasis; with most hemorrhage behind the pancreas, in the tissue about the gland. There was no evidence of any inflammation of the pancreas. After reviewing the literature and describing a number of experiments upon the liver and pancreas, Chauffard and Ravaut conclude without giving a satisfactory explanation for the occurrence of hemorrhagic pancreatitis in typhoid fever. Perhaps the lack of nourishing food during the fever and the activity of the pancreas necessary during convalescence, from the stronger food ingested, may account for the possibility of hemorrhagic pancreatitis. [M.O.]

3.—After three experiments, with control tests, of human blood mixed with typhoid bacilli, Maurel concludes that **human leucocytes absorb typhoid bacilli**, but succumb to this absorption in less than a half hour; therefore this bacillus is one of the most virulent for the human leucocytes; that in these experiments the leucocytes have never sought or fled from the bacilli; that only the absorption of the bacilli, and not of their products, is dangerous to the leucocytes; that fever from 103 to 104° F. is favorable to the leucocytes in their struggle with the bacilli; and that the typhoid bacilli precipitate the fibrin of the blood, but much less than certain other micro-organisms. Under the influence of the conditions in which these experiments were performed, with little oxygen, and some contamination of the surroundings, the number of typhoid bacilli decreased rather than increased; whence he concludes that such conditions are unfavorable to its development. [M.O.]

4.—Collet and Gallavardin report a case of massive primary tuberculosis of the spleen, a man of 60, in whom a tumor had existed for two years in the left hypochondrium. For two months gastric symptoms have been frequent. He has lost 20 pounds. Examination showed a spleen which reached into the left hypochondrium as far as the spinous process of the ilium. It was nodular, but not tender. The liver extended four finger breadths below the margin of the ribs. There was slight fever, but no cachexia or malaria. Bacteriologically and microscopically, after autopsy, massive primary tuberculosis of the spleen was found, which, when inoculated in a rabbit, produced giant cells. The liver was also tuberculous, and an old calcareous tubercle was found at the apex of one lung. This was a case of the spleno-hepatic, not purely splenic, nor were the lymph-glands affected. The literature of the subject is fully reviewed. [M.O.]

5.—Early in the eighteenth century Lambert advised suturing arteries. In 1757 it was first attempted. In 1889 Jassinowsky first succeeded in obtaining permeability of the sutured vessel. Thus far sutures applied to join arteries which had been cut clean across have failed. This procedure is still in the experimental stage. Glück covered the artery, after suturing the ends together, with a cuff formed by a fresh vein or artery sutured about it. Brian and Jaboulay turn out the edges of the apposing cut ends, and apply sutures tightly through the edges. Murphy invaginates one end in the other, suturing both ends, but not passing the sutures through into the lumen of the vessel. Bouglé, after numerous experiments upon the arteries of dogs, finally sutured the ends of cut arteries together with sutures which did not pass through the walls into the lumen of the vessel. He found that investigation

was not necessary. He advises arterial suture in man should opportunity present. [M. O.]

6.—Morel and Dalous have performed a series of eight experiments upon rabbits to study the **histogenesis of the tubercle**. From their minute and detailed observations, after the staining of many slides and the preparation of many sections, it is shown that in the alveoli of the lungs and the bronchial cavities, **tubercles develop exclusively at the expense of the leucocytes**, especially those large mononuclear cells which arrive quickly at each focus of infection. The fixed cells of the alveoli and the epithelial cells of the bronchial walls play absolutely no role in the histogenesis of the tubercles. [M. O.]

7.—Troisier and Letulle have made further researches upon **carcinomatous lymphangitis of the lungs**. They describe specimens of an epithelioma of the lymphatics secondary to visceral cancer. The thoracic duct is the last part of the lymphatic system to become affected. The vessel invaded becomes a thick, gray, or yellow cord, its lumen obstructed by a caseous mass of cancer cells. On the thoracic duct cancerous nodules may appear, as the lymph-glands become involved. Sections of the preparation are described. [M. O.]

REVUE MEDICALE LE L'EST.

April 1, 1901. 28me. Année, No. 7.)

1. Histology. A. PREUAUT.

1.—**Histology** is no longer the simple study of the cells which form the tissues. It is rather a general anatomy and physiology from the comparison of structure and function observed. Two theories have been proposed to explain histology, the classic vitalist theory, and the modern physico-chemical theory. For while the structure studied is living, it is composed of chemical matter, constituted physically. A histological structure is what is actually observed in a tissue or cell. A cell is an elementary, well limited, organism, living alone or in association with others. Protoplasm, a term formerly much used, no longer holds a place in histology. It is but a morphologic idea, seen only through the microscope. Physically it cannot be found. Living matter possesses the faculty of changing its substance, its form, and its energy. But these changes are possible in bodies that are not alive, and have been shown to be purely chemical in character. Thus the early vitalist theory has been disproved, while the physico-chemical theory not only is better understood, but is now considered the only scientific theory. With physiology, histology, reduced to physics and chemistry, joins the vanguard of biology. [M. O.]

REVUE DE CHIRURGIE.

April, 1901. (21me. Année, No. 4.)

1. Hemothorax. TH. TUFFIER and G. MILIAN.
2. Hydatid Cysts. HERRERA VEGAS and DANIEL J. CRANWELL.
3. Fractures of the Upper Jaw. RENE LE FORT.
4. The Perihepatic and Pleural Complications of Appendicitis. L. LAPEYRE.
5. Primary Tuberculosis of the Parotid. P. LECENE.
6. Genital Tuberculosis in Women. MARIE GOROVITZ.

1.—A man of 37, neurasthenic and syphilitic, in an attack of hypochondria tried to shoot himself through the heart. The bullet entered about the nipple and lodged posteriorly, near the angle of the scapula, where it could not be palpated. No suppuration occurred and the wound healed by first intention. But on the day after the accident slight **hemothorax** was found, without pneumothorax. The further evolution of this hemothorax has been most carefully studied. The liquid has been frequently examined bacteriologically, its red and white corpuscles counted, and cover-glass preparations made. Up to the 21st. day, the liquid increased in volume but was less dark in color; then the dulness began to diminish and the effusion grew perceptibly lighter. By the 38th day it was yellow. On the 44th day, when the patient left the hospital, there was but three or four finger-breadths of dulness remaining. Fever disappeared on the fifth day to return two weeks later, with

a gradual rise to 101.5°F. From the bacteriological examinations, no bacteria at any time developed. The process was absolutely aseptic. The red corpuscles in the fluid began to disappear on the 18th day, and were almost gone on the 32nd. From the cover-glass preparations it is seen that the total number of leucocytes fell on the 18th day from 6000 per c.mm., reaching 1300 on the 26th day. On the 37th day they were 2700, but on the 44th, 1500 again. The polynuclear leucocytes fell on the 16th day from 2600 to practically nothing on the 26th day. The later increase in the leucocytes was due to the lymphocytes. The following conclusions were drawn by Tuffier and Milian: the increase in the effusion about the 15th day is not due to hemorrhage, but to a serous exudate, as is easily shown by puncture. This is therefore not a cause for operation. Nor is the fever which moderates in a few days an indication to operate. But persistence of the **polynuclear leucocytes in the effusion after the 21st day will suggest suppuration**. Should the polynuclear leucocytes fail to decrease from day to day, remain stationary, or increase, suppuration is to be suspected. The correct treatment for traumatic hemothorax is withdrawal of the fluid about the 15th day, when the bloody effusion is well diluted, and the pulmonary wound has sufficiently healed to prevent renewed hemorrhage on removing the pressure of the liquid in the pleura. [M. O.]

2.—During the past 13 years, 952 cases of **hydatid cysts** have been recorded in the Republic of Argentine. Vegas and Cranwell believe that as many as 1500 cases have occurred. 914 cases were seen in Buenos Ayres, 173 in one year, 1898. The causes of this frequency of hydatids is probably the immense number of cattle and dogs in Argentine, most of which have hydatids. Of the 952 cases recorded, hydatid cysts appeared 641 times in the liver, 54 times in the lung, 30 times in the spleen, 26 times in the cellular tissue, 25 times in the female pelvis, and 21 times in the mesentery. There were also multiple cysts in the abdomen in 21 cases. 27 cases had cysts in two different organs. The liquid in hydatid cysts may be aseptic, the pericystic membrane containing the germs; the liquid, even though clear, may contain the germs; or, as the liquid is an excellent culture medium, it may contain streptococci, staphylococci, colon bacilli, or typhoid bacilli. The mortality from hydatid cysts, with operation in almost all cases, is 11.11%. The most dangerous cases are multiple cysts of the abdomen or brain. The operation to be preferred is the slow but sure method, **marsupialization with drainage**. In rare cases, in hydatids of the brain, etc., extraction of the cyst with its entire membrane, without drainage, is done. [M. O.]

3.—The upper jaw includes most of the bones of the skull and face. Partial fractures are quite common in the nasal and superior maxillary bones. (palatine or orbital.) They may result from gunshot or sabre wounds. **Fractures of the upper jaw** may be direct, occurring at the point of injury, or indirect, occurring at a distance from the point of injury. Direct fractures are generally limited; yet an indirect fracture may accompany a direct fracture. Both kinds of fractures are due to severe injury, and show no displacement. Le Fort's experiments, 35 in number, were made upon the cadaver. They include fractures due to violence applied anteriorly at the level of the upper lip; laterally on the lower part of the superior maxilla; from below upon the superior maxilla; anteriorly upon the lower part of the face; from above upon the root of the nose; from below upon the inferior maxillary and malar bones, either laterally, the head not being supported, or the moving head striking a resisting body; anteriorly upon the malar bone, the head resting on the occiput; externally on one malar bone, the head resting on the other; or anteriorly upon the front of the face. They may also result from force applied to the face and skull together, or to many blows in different parts of the face from different directions. Seven cases are reported from the literature, and one of his own. Le Fort believes that the position of the superior maxillary bones, with the malar bones, at the base of the skull, is the cause of the frequent fractures. Two lines of weakness, a protection for the skull, extend across these bones of the face. Three fragments may be found, generally immovable, the alveolar arch, the malar bone, and the upper end of the maxilla with the nasal bone occasionally. Le Fort concludes that in fracture of the upper jaw, the character and signs of the fracture will be simple and similar to one another, no matter whence

the violence came. He hopes that this may aid in forming a precise diagnosis of these lesions, so difficult to determine. [M. O.]

4.—Will be abstracted when completed.

5.—Primary tuberculosis of the parotid gland is very rare in man, Lecène having been able to collect but 8 authentic cases with histological and bacteriological examinations reported. Lecène reports the case of a man of 29, with a tumor of the right parotid which had existed 10 years, slowly growing in size. There was no pain, but great inconvenience on moving the head. The skin was normal, over a tumor about the size of a large nut. It was hard internally where it was attached to the parotid, softer and almost fluctuating under the skin. There were no signs of tuberculosis elsewhere. It was diagnosed a mixed tumor of the parotid, and was operated, the tumor being enucleated. Twelve days later he left the hospital. The wound healed quickly, and there has been no recurrence. Preparations reveal typical giant cells, with tubercle bacilli. A review of the meager literature follows. The treatment of tuberculosis of the parotid is wholly surgical. [M. O.]

6.—Will be abstracted when concluded.

RUSSKI ARCHIV PATOLOGII. KLINITSCHESKOI MEDICINII BAKTERIOLOGII.

March, 1901. (Vol. 6, No. 3).

2. Iron in the Liver of Healthy Persons. P. BIELFELD.
3. A Case of Affection of the Skin in Pseudoleukemia. S. K. KIRKOROFF.
4. Morphologic Observations on the Pathogenesis of Tumors. I. G. SAVTCHENKO.
5. On the Changes in the Ganglia and Muscle of the Heart, in the Liver and Kidneys Produced by Poisoning with Digitalis. N. KLOPOTOVSKI.
6. Contribution to the Study of Tumors of the Corpora Quadrigemina and Some Points in the Differential Diagnosis from Tumors of the Cerebellum. V. V. NISSEN.

1.—Kichensky reports a rare case of primary squamous carcinoma of the calyces, pelvis and ureters with subsequent invasion of the kidneys, liver, adjoining diaphragm, peritoneum and metastasis into the right knee. The patient was a woman, 32 years old, and was sick only 1½ months. The peculiarity of the growth was that wherever found it possessed the character of the epithelium from the urinary tract and showed a tendency to horny metamorphosis, thus resembling the epidermis. A complete description of the pathological findings as well as a thorough review of the literature on the subject are given. [A. R.]

2.—Bielfeld made a number of analyses of normal liver substance with a view of determining whether the hepatic cells contain iron. He claims that most of the authors who preceded him in the investigation employed faulty methods which were responsible for the discrepancy in their results. The method employed by him was that devised in the laboratory of Alex. Schmidt and is performed as follows: After removing the gallbladder the liver is cut into small pieces, ½ cm. thick, by means of a piece of glass. Both surfaces of each piece are scraped with a horn-spatula, the scrapings mixed with salt solution (7:1000) and strained through a clean piece of linen. The contents of the strainer are washed 2-3 times with the salt solution. The liquid which passes through the linen consists of liver cells suspended in the salt solution. This liquid is then placed in a cylinder of a capacity of 10 liters which is filled up to the brim with salt solution and set aside in a cool place (0-10) for 12 hours. By that time the liver cells have subsided. The salt solution is renewed from 3 to 6 times until the spectroscope fails to show bands of hemoglobin. When the washing is completed the fluid is decanted and the solid portion subjected to centrifugation to remove the last portions of fluid. The liver cells are then dried to a constant weight and divided into two parts; one for determining the amount of sodium chloride, the other for the determination of iron. Both parts are incinerated. The sodium chloride in one is determined by Mohr's method, while the other is washed with hot water, filtered, again

incinerated, together with the filter, the ashes dissolved in hydrochloric acid, the latter evaporated, the residue treated with sulphuric acid and a piece of zinc added to convert the iron into an oxide, and the amount of the latter is determined by titration with standard permanganate solution. The conclusions arrived at by the author after a considerable number of analyses are as follows: (1) The amount of iron contained in the hepatic cells in health are subject to considerable variation. (2) The average amount of iron present in a normal liver is 0.169%. (3) There is more iron in the liver of men than women. (4) The amount of iron in the liver cells is increased in old age. (5) It is less between the ages of 20-25. [A. R.]

3.—Kirkoroff reports the autopsy of a case of pseudoleukemia with cutaneous involvement. The lesions in the skin resembled lymphosarcoma. The condition is quite rare, only a few cases having been reported. [A. R.]

4.—Savchenko takes up the consideration of the morphology of tumors with a view of throwing some light on the subject of parasitology. By the use of special fixing reagents and stains he demonstrated morphological cellular elements which are not to be found in normal cells. Specimens of elasto-fibroma fixed in Flemming's solution and stained by the ordinary aniline dyes showed intracellular bodies varying in size from that of a micrococcus to a red blood corpuscle. They were neither mucoid, colloid or hyaline in character and could easily be mistaken for parasites, but upon further examination by the aid of differential stains they proved to be elastogenous elements which accumulated in the protoplasm of the cell after it ceased to perform its proper function. The suggestion is made that in other tumors the presence of intracellular bodies may be explained by considering the latter as abnormal products of cells possessing perverted function. In certain specimens of sarcoma fixed in Flemming's solution and stained by the Biondi method intracellular formations were observed which resembled closely the parasites of cancer described by different authors. The author is continuing his studies and promises future communications on the subject. [A. R.]

5.—Klopotovskii studied the effects of poisonous doses of digitalis on the heart, liver and kidneys of dogs. An infusion of digitalis or digitalin was used. In acute poisoning the nuclei of the cells of the cardiac ganglia are more or less destroyed, the bodies of the cells are increased in size and lose their structure. In subacute poisoning the cell-body is retracted and the protoplasm becomes homogeneous or finely granular. This change is still more pronounced in chronic poisoning (8-15 days) with the additional formation of vacuoles and oil globules within the protoplasm. In the cardiac muscle fragmentation, effacement of the striation and fatty degeneration take place. The liver shows passive hyperemia, atrophy of the cells, vacuolization and fatty degeneration of the protoplasm. The kidneys show albuminous and fatty degeneration varying with the period of intoxication. [A. R.]

6.—Will be abstracted when completed. [A. R.]

Nodular Erythema, Rheumatic Purpura, and Hydroa.—At a clinic given recently by Dr. DuCastel at the Saint-Louis Hospital in Paris, (*Medicine Moderne*, 1901, No. 19), a patient was presented, with the three skin lesions associated. Two weeks before, she felt ill, had a chill and fever, followed by the appearance of the eruptions. There were patches of nodular erythema upon the legs, the size of a dime, round or oval, elevated, and red, disappearing on pressure. There is generally some pain with it. Then appeared the petechiae of rheumatic purpura upon the arms and legs. With this, too, there is some pain, generally about the joints, with edema. It appears in successive crops, each lasting about a week. Hydroa, or hydroic erythema, is an eruption composed of erythematous spots in the center of which localized edema is found. It appears suddenly and lasts a week or more. DuCastel believes that all three eruptions are due to vascular congestion in the skin, with some tendency to edema. The common cause is either an infection or an intoxication, probably. It is possible that a toxemia, from unknown reasons, will act differently upon the skin of different parts of the body. He recommends quinine and sodium salicylate internally, with soothing moist applications and a dusting powder locally, as treatment. [M. O.]

THE TOPICAL TREATMENT OF FOCAL AND JACKSONIAN EPILEPSY.*

By J. WILLIAM WHITE, M. D.,
of Philadelphia.

John Rhea Barton Professor of Surgery, University of Pennsylvania.

Before describing a method of treatment which may prove to be appropriate to those forms of epilepsy in which a distinct motor center is involved, and recording the results up to this time in the only two cases in which I have tried it, I desire to state briefly the line of thought which led me to make the experiment.

I may assume without argument that the following propositions would be generally accepted as correct: 1. The essential cause of epilepsy, exclusive of demonstrable sources of brain irritation—as tumors, bony outgrowths, depressed bone, foreign bodies, tuberculosis or gummatous infiltration—is unknown.**

2. What seems to be certain is that, whatever the cause, a greater or less area of the cerebral cortex is in a condition of unstable equilibrium, in which normal physiological action in response to normal stimuli is transformed into excessive and irregular outbursts of motor and sensory phenomena.

3. That it is the universal experience that this condition is aggravated by irritation or excitement of all sorts, and that the only drugs that have a fairly uniform controlling influence are those which, like the bromides, are cerebral sedatives, and diminish temporarily both reflex excitability and normal physiological activity.

4. That in all forms of epilepsy medical and hygienic treatment, though occasionally producing good results in isolated cases, is unsatisfactory; and that this is also true of surgical treatment except in the not very frequent cases where a physical cause that is removable is discovered.

In the excellent article (already quoted from) on the modern treatment of epilepsy, Dr. Clark says: "Without doubt the greatest single drug in the treatment of epilepsy is some bromide salt," and adds that to be effective in chronic cases, such salts must be given in large daily doses (from 300 grains upward) and should not be discarded until "salt starvation" or "semi-salt starvation" had been tried as an adjuvant.

As to surgical treatment, he makes the following very sensible remarks, with which I entirely agree:

*This report is published simultaneously with its appearance in the University of Pennsylvania Medical Bulletin.

**In an article on the modern treatment of epilepsy, Dr. Pierce Clark records as follows, the pathological findings in thirteen selected cases:

A degeneration of the nucleus of the second or so-called sensory layer; further, a willingness for the nucleus to suffer extrusion from the nerve cell; a chromatolysis of the whole cortex, especially in the motor region; phagocytosis of the constituent nervous elements by infiltrating leucocytes, and last of all, in the most progressive cases, a nodular or disseminated sclerosis, new formed under what is usually termed degenerative repair, a proliferation of the neuroglia. The cortical sclerosis was unevenly distributed and was probably the last and permanent set scene of this disease, played in the gray mantle of the epileptic brain."

He adds: "If these lesions should be found to be constant, to what extent would they solve the epilepsy problem? They would prove only that epilepsy is accompanied and followed by a definite organic lesion of a marked and widely degenerative nature. The lesions are probably both a cause and an effect of the disease. We would know that the nervous storm had occurred and left a tract of destruction, but our knowledge of the exciter of the storm and the degree of resistance it had met from the tissues, would be but little or not at all enriched."

"The rules which govern the selection of cases for trephining need to be more restrictive than at present conservative medicine demands. If this were done, a much better prognosis for recovery would obtain for the traumatic cases than the present 4 per cent. From the class of those heretofore supposed to be operable, I would urge that idiopathic epileptics in whom the seizures have a definite form of invasion be withdrawn. True or essential epilepsy frequently takes the Jacksonian form in point of muscular involvement in seizures. Many traumatics probably owe the focalization of their convulsions as little to trauma as the true idiopathics with Jacksonian convulsions. The brain, as a whole, in such cases is epileptogenetic, one zone is only a little more excitable than another. Much disappointment has been experienced by surgeons operating upon these idiopathics disguised as Jacksonian epilepsy."

Taking the above group of facts as a basis, I was influenced to try the method of treatment I am about to describe, by some other facts that had attracted my attention years ago; especially the influence of operation upon epileptics in whom nothing abnormal was found at the time of operation, or in whom the abnormality had no definite relation to the epilepsy. In 1891, in a paper entitled "The Supposed Curative Effect of Operation Per Se," (*Annals of Surgery*), I published a series of tables containing 172 cases of epilepsy, 147 of which had been subjected to operations of extraordinary variety, and with the equally extraordinary result, according to the operators, of "improving" or "curing" a large percentage of the cases. In 56 cases of trephining, nothing abnormal having been found to account for the symptoms, 25 were "cured," 18 "improved." In 30 cases of ligation of blood vessels, 14 were "cured," 15 "improved." In 10 cases of castration, all were "cured." In 9 cases of tracheotomy, 2 were "cured," 6 were "improved." In 24 cases of removal of the superior cervical sympathetic ganglia, 6 were "cured." In 6 cases of incision of the scalp for exploration (nothing abnormal being found), all were "cured."

Twelve cases of epilepsy are reported as "cured" by such operations as stretching of the sciatic nerve, excision of the musculo-cutaneous nerve, cauterization of the larynx (2), circumcision, application of a seton to back of neck (4), tenotomy of external recti, burning of scalp, puncture of heart, etc.

Many of these cases were reported too early to be of much use as evidence of a genuine and permanent disappearance of the disease, or even a lasting amelioration of the symptoms. Hence, I have put the words "cured" and "improved" in quotation marks. But, even admitting this, it is a remarkable showing which is deserving of more thoughtful consideration than it has yet received. That out of 147 cases submitted to diverse operations (which in the great majority of cases revealed nothing to account for the symptoms), 124 should have been apparently so much benefited that they were recorded as "cured" or "improved," is certainly extraordinary, even after due allowance has been made for the invincible and not unnatural tendency of the profession to put on record chiefly its favorable results. But when we find that in 25

of these cases the improved condition was present after the lapse of twelve months, it is evident that something which had at least a beneficial tendency in many cases occurred as a result of operative interference. When I tried to account for this, I was able to conceive of but four possible explanations dependent on the four following conditions, which were common to all, or nearly all, of the cases:

1. Anesthesia, on the theory that by its volatility or diffusibility the anesthetic might reach the nerve centers in sufficient quantity to destroy a possible microbe or neutralize an equally hypothetical toxin.

2. Psychical influence or so-called mental impression.

3. Relief of tension.

4. Reflex action or the "reaction of traumatism."

These influences were operative in the majority of the cases, although not one of them, except the last, applies to the whole list.

1. That *anesthesia* was not the factor producing the improvement was shown by a series of observations made by me upon a number of epileptics in the ward for nervous diseases of a large hospital. All other treatment having been withdrawn and the cases kept under observation for a time, ether was given to the production of full anesthesia at intervals of from forty-eight to seventy-two hours. The results were either entirely negative or the patients grew worse in consequence of the withdrawal of their bromides, and after a trial extending over some weeks and in a considerable number of cases, I satisfied myself that anesthesia alone produced little or no effect in either the severity or the frequency of epileptic convulsions. In the majority of these patients the disease was, of course, of the idiopathic variety, but it must be remembered that in cases of supposed traumatic epilepsy in which nothing abnormal is found on operation the diagnosis has probably been incorrect, and the type of the disease is really idiopathic. The error is facilitated by the frequency with which scars and other relics of former traumatisms are found on the scalps of epileptics, injured during their convulsive attacks.

2. The possible effect of *psychic influence* (through imagination and mental impression) is not so easily dismissed. There is no doubt that it is possible through influences acting upon the emotional or intellectual nature to affect the organic processes of secretion, nutrition, etc., and that it is therefore conceivable that through the same influences pathological change may be arrested and reparative or curative action established.

The normal equilibrium which we witness between the cerebro-spinal and the sympathetic systems, as respects their influence upon the blood vessels, is obviously more or less interfered with, when the brain transmits a more than wonted impulse, allowing the unrestrained action of the sympathetic vaso-motor nerves or paralyzing their influence.

When this equilibrium is already unbalanced and abnormal, it may be that such interference through the emotions may have at least a tendency toward the re-establishment of healthy conditions. This is vague, but cannot on account merely of vagueness be dismissed from consideration. A reference

to the paper I have quoted above (*Annals of Surgery*, August and September, 1891) will show that examples of marked physical effects of purely psychic impressions are numerous, and that, through this agency, cures of disease dependent upon actual pathological conditions, must be admitted to be possible.

3. *Relief of tension* can hardly be considered as a factor in this relation. The added tension in epilepsy follows the convulsion. There is no evidence that it precedes it, or is in any sense a chronic cerebral condition associated with epilepsy.

In cases that were not drained after trephining, the relief of tension can scarcely be a factor in the resulting amelioration. In cases that are drained, as in some recently reported by Kocher, the reflex element (or the element of counter-irritation or of the "reaction of traumatism") is co-existent and complicates the problem. This is further complicated by the fact that nearly all cases receive post-operative bromide treatment.

4. As to reflex action, or the reaction of traumatism, Verneuil, in a paper calling attention to the influence exerted by prior lesions of the liver on the progress of traumatic lesions, long ago emphasized the fact that any traumatism, however slight, sometimes excites in the entire economy a general perturbation and sometimes by a kind of selection of the weak point a sudden and violent aggravation of lesions that were only slight or that slumbered.

It seems to me that this same excitement, usually prejudicial, may occasionally be curative, although it must be admitted that these also are vague terms, and that even if the explanation is correct, it is yet far from final.

In view of all the conditions and possible factors thus described, the problems finally took this shape in my mind:

1. Can the subjects of this distressing and intractable disease receive without undue risk to life or general health the benefit of both operative interference and sedation of the affected brain area?

2. Can operation be based on any but empirical grounds? If on the latter only does the evidence warrant its continuance?

3. Is there any means of securing sedation (i. e., of applying the general therapeutic principle of rest in such a way that natural processes may have an opportunity to effect a cure), without at the same time depressing or greatly interfering with the general health?

I may say at once that as regards idiopathic epilepsies and the pseudo-Jacksonian cases already described, the answer to all these queries should, with the evidence now before us, be in the negative.

There remain for consideration the true focal or Jacksonian cases, whether traumatic or not.

In these the results of operation, while more encouraging, are, in my opinion, not sufficiently so to justify us in ignoring the greatly increased risk and the post-operative paralysis following excision of the epileptogenic center, without which the trephining becomes an incomplete and unsatisfactory operation. Clark says (and my observations lead me to endorse his statement):

"Idiopathics in whom seizures are of the Jacksonian type, should be trephined only when infan-

tile cerebral palsies can be excluded, and when the family and personal degeneracy is at a minimum." He adds, however, "if operation is determined upon in such cases, a very thorough removal of the epileptogenetic area should be made; even then but a fraction of one per cent. recover from their epilepsy," and he might have added that the operation, apart from its crippling effect, is sure to have a considerable mortality.

It was to lessen this risk to life and to try to secure the chance, however slight, of cure or amelioration without paralysis of important muscular groups, or of entire limbs, that I was led to consider, and finally to employ, the method, which may be described as follows:

The affected center is, of course, determined in advance by the most careful study and observation of the case. Its relation to the cranium is indicated by a silver or iodine mark upon the shaven scalp two days before the operation. The scalp is sterilized and re-sterilized three times at intervals of twelve hours, not only before the trephining, but also before each subsequent application of the treatment. A horse-shoe-shaped flap is raised and a half-inch button of bone removed with a small trephine. The dura is left intact. Thirty minims of a sterile two per cent. solution of eucaïne is then injected into the brain substance at the center of the trephine opening, the point of the needle being introduced about three-quarters of an inch. The needle is gradually withdrawn as the last ten minims of the solution are injected. The flap is replaced. The patient is returned to bed, and on the day of operation, and the following day, should receive full doses of bromides. At intervals, the proper length of which can only be determined by experience, the scalp having been sterilized as above, the injection is repeated. The patient should be kept in bed at least four hours after each injection and should take bromides for from one to two days.

In giving these directions, I beg to be understood as merely submitting the method to the profession for further trial and elaboration, or, perhaps, for rejection. I am not myself convinced that it has any real value.

I append from the records of the University Hospital the histories of the two cases in which I have tried it. In the first of these cases the prominence of pain as a symptom led me to disregard the contraindication furnished by the history of infantile paralysis:

CASE 1.—White, male, Aet. 24.

Admitted to the service of Dr. H. C. Wood at the University Hospital, February 15th, 1899.

There was nothing in the family history which had any bearing upon his condition. At the age of six months it was found that he had infantile cerebral paralysis affecting the right arm and right leg. He began to walk when between two and three years of age, but has always limped as a result of defective development. His first epileptiform attacks began at the age of twelve, affecting the right arm and leg, and always occurring at night. They are associated with sharp needle-like pains starting near the shoulder, passing down the right arm, and then felt in the upper part of the right thigh passing down the leg. These are very severe, and are apt to be accompanied by an outcry. At, or about this time, there is usually a short general tonic spasm followed by clonic convulsions. Each attack lasts four or five minutes. He has never fallen down or bitten his tongue or lost consciousness. During the day the attacks never go beyond the pain in the

arm. He complains of a continual needle-like pain in the right arm, which he thinks he lessens by wearing a tight rubber band around the wrist and hand. He also thinks that this helps in aborting the attacks. There was no evidence of any organic disease.

On March 9th, having had four attacks in the interval, and having been carefully observed, he was transferred to Dr. White's ward for operation.

On March 11th, the operation was performed (see description above). The injection was made directly over the centre for the arm. After operation, the pain in the arm had disappeared.

On the 12th, an epileptic convulsion occurred which is noted as peculiar in the following respects: It was not painful; it had no aura; it began in the upper part of the arm as before but did not involve any muscles outside the arm; it lasted but two minutes, and was not accompanied or followed by any mental phenomena or by sleep.

Between March 12th and June 24th, the patient remained under observation in the Hospital, receiving during this time five intra-cerebral injections, the quantity varying from ten to fifteen minims, the eucaïne being increased first to four and then to six per cent. During this time (fourteen weeks) he had eight convulsive attacks, but with one exception they were all milder than those that had preceded the beginning of the treatment, and there was throughout a greatly lessened complaint of pain.

He was readmitted to the Hospital on October 10th, 1899. On that day the following note was made: Has had four attacks since his discharge, but they were not nearly so severe as formerly, and were not accompanied by so much pain. He has now some motion in the hand and arm, which he says he did not have before. He took potassium bromide about 3ii in a week during the summer.

On the 17th, he had his first convulsion, which was fairly severe.

On the 18th, fifteen minims of a two per cent. solution of eucaïne were injected as before. No beneficial effect was observable. In fact, he had a series of very slight convulsions during the next five days.

On November 1st, 10th, and 18th, and on December 8th and 21st, these injections were repeated. During this time he had three convulsions of very slight gravity. He was discharged again on December 21st, having had no attacks or threatenings for two weeks.

On January 15th, 1900, he was readmitted on account of an attack which he had on the 10th.

On the 20th, fifteen minims of a four per cent. solution were injected.

On February 5th, he was discharged, there having been but one convulsion in the interval.

On June 12th, 1900, there having been no attack for thirteen weeks, he received one injection of twenty minims of two per cent. solution.

On October 6th, 1900, the treatment was repeated, he having had but one slight convulsion in the interval.

On December 1st, 1900, the treatment was again repeated. He had had several threatenings in the interval, but upon the administration of an emetic, the premonitory symptoms had disappeared without an attack.

CASE 2.—White. Male. Aet. 37.

Admitted to the service of Dr. C. Wood, May 5th, 1900.

There was nothing in the family or previous personal history having any bearing upon the condition.

In June, 1899, he had a feeling like a shock in the right arm, and it became rigid in a semi-flexed position. This was the first attack of the kind he ever had. For about a year previous to this, he suffered from a constant dull pain in the region of the frontal sinuses. This still persists.

The attacks have continued to the present time, occurring at intervals of one or two a week, to one every two weeks. They usually occur after he has gone to bed. Almost always for several hours prior to an attack the pain in the frontal region is worse, and there is usually in the right arm a strange feeling, which he cannot describe. After he has gone to bed, the attack comes on suddenly with a feeling like an electric shock in the right arm which becomes rigid with the forearm flexed not quite at a right angle. The spasm is clonic, and lasts from a few seconds to a minute, or a minute and a half (the longest). After the attack is over there is no drowsiness, or pain in the arm, and the headache is usually much better.

He has never become unconscious during an attack.

There is no pain in the arm during the attack, but it is numb.

On May 20th, he was transferred to Dr. White's service. He was kept under observation until June 1st, during which time he had three attacks. On that day trephining was done, and thirty minims of a two per cent. eucaine solution were injected into the arm centre. He was kept under observation for two weeks, and having no symptoms whatever, was then permitted to leave the hospital.

He was readmitted on January 22nd, 1901, at which time the following note was made:

Since discharge on June 13th, 1900, patient has returned to the hospital three times in order to receive the hypodermics. The first hypodermic was five weeks after discharge. Previous to that and following it, the intervals averaged between fifteen and eighteen days. (Previous to the operation, seizures were every two or three days, the maximum interval being nine days). Six weeks later the second hypodermic was given. Intervals between seizures were from fifteen to eighteen days. Two months later he returned for a third hypodermic (latter part of September). Since then the attacks have averaged about the same. He has gone twenty-three days without an attack. On December 28th he had five attacks, coming on an hour apart, each successive attack being lighter. On December 29th, he had four attacks, lighter than on 28th.

On December 30th he had three attacks; lighter than on the 29th.

On December 31st, he had one attack, lighter than on the 30th.

He was under no excitement at this time.

Last attack was on January 18th, 1901. This attack was severe, lasting thirty to forty seconds.

Operation by Dr. White, January 23rd, 1901.

Thirty minims of a two per cent. solution of eucaine were injected into the brain, and a collodion dressing was applied. Patient was returned to the ward. Fifteen minutes after the injection patient complained of nausea and a sensation of numbness in the right arm and leg. One hour and a half after the injection he was taken with a convulsive seizure which involved the whole right side, with the exception of the face. The leg and arm were thrown about violently and the patient made frequent outcries. He was in a semi-unconscious state and did not answer questions coherently. This seizure lasted four minutes. Following the attack the patient complained of headache and a sensation of numbness in the right half of the body.

On January 24th, 1901, the final note which follows was made: Until this morning patient still complained of feeling of numbness in the right side. States that the attack he had yesterday was the most severe one he had ever had, and that it differed from his usual attacks in that it was a general seizure. At present he feels perfectly normal, and is discharged.

He has not since been heard from.

It will be apparent to any one who reads these cases critically that they cannot be said to establish even the entire safety of the procedure, as the convulsions in Case 2, which followed one of the injections, were of very marked severity. Neither can it be said that the results obtained were noticeably better than have seemed to follow the very miscellaneous operative procedures which I have mentioned above. It still seems, however, that there are possibilities of benefit by this line of treatment which justify me in placing it conservatively, as I have tried to do, before the profession.

Hospital at Cesarea.—The first meeting of the Board of Trustees of the American Christian Hospital at Cesarea, Asia Minor, was recently held in Albany, N. Y. The officers elected are: Allison Dodd, president; Samuel T. Carter, Jr., vice-president; Charles E. Manierre, secretary, and James M. Speers, treasurer.

The board was incorporated to hold the property and give perpetuity to the work of the Rev. William S. Dodd, M. D. The small dispensary over a stable with which he began in 1886 has now grown to a fine stone hospital building of three stories, capable of accommodating seventy beds.

THEORETICAL AND PRACTICAL CONSIDERATIONS ON THE TREATMENT OF JACKSONIAN EPILEPSY BY OPERATION; WITH THE REPORT OF FIVE CASES.

By JAMES JACKSON PUTNAM, M. D.,

Professor of Neurology, Harvard Medical School.

The necessity of giving advice as to the propriety of cortical excision and of operation in general, in a case of non-traumatic focal epilepsy which came recently under my observation, has led me to review the literature bearing on this interesting disease, and to scrutinize afresh the results of my personal experience.

It is now more than a quarter of a century since Hughling Jackson first divined the localization-mosaic of the Rolandic convolutions, and many years since Horsley, well trained by experimental research, had the courage to attempt with the knife the solution of the question whether one may argue that epileptic seizures which begin with a "signal symptom" are due to localized—possibly removable—forms of disease.

This problem is still, and will perhaps long remain unsolved, but each new decade brings fresh data to renew the interest of the inquiry, as waves of hopefulness or discouragement succeed each other in the professional mind. Among the more recent advocates for the view that focal disease, discoverable only by the microscope, may be the cause of so-called "focal epilepsy," and that the removal of portions of the cortex containing this altered tissue and constituting the "center" corresponding to the initial symptom of the fit, may, if done early enough, cure the disease, is Dr. Joseph Collins (1), who discusses, in the autumn number of *Brain*, 1896, the histological changes in two interesting cases, where thorough excision had been done by Gerster and by Curtis. A private note from Dr. Collins states that one of these patients has remained free from disease up to the present time, that is, for six years since operation. In the first case the pia mater was thickened and adherent to the altered cortex; in the other only degeneration of the large ganglion cells was found. Collins speaks (page 384) of this diseased tissue as having been "entirely removed," but in regard to this point, one may be permitted to feel a grave doubt which cannot be removed by any evidence that the case has thus far furnished. And this to my mind is an important matter, because if similar tissue has been left behind, the anatomical conditions for a renewal of the epileptic attacks still exist, and if the attacks do not recur we may have to seek the explanation in the inhibitory effects of the operation, and then the question arises whether similar effects might not have been produced by less severe measures. Certainly there is an abundance of evidence that fits may cease, or fail to occur, in spite of the presence of persistent sources of irritation.

The object of this paper is to consider some of the questions here involved, which I will state as follows:

1 Dr. Collins expressly repudiates any desire to generalize on the basis of these cases, and it is not here intended to imply that he does so.

1. Is the removal of disease-foci involving the cortex of clinical value?

2. Does the removal of the cortex itself, when apparently unchanged, add an influence of material importance?

3. How are the results of such measures as these best to be explained, and, especially, is the benefit obtained from cortical excision necessarily due to the removal either of a focus of disease or of a special "discharge-focus"?

4. What additional light has been thrown, by recent experimental researches and clinical observations, on the physiology of the cerebral cortex?

The views which I shall maintain are, (1) that operations of many different sorts are of value; (2) that the beneficial action of these operations, although complex in character, is mainly due to the induction of a temporary inhibition of the morbid action of the cortex, which permits of the establishment of a more normal tendency; (3) that the removal of the apparently normal cortex is rarely advisable, and, when beneficial, acts mainly as above indicated; (4) that the cause of the persistence of the "epileptic habit" is not to be sought alone in anatomical peculiarities of the brain, but that it shares the vitality and independent endurance of memories in general. Also, the symptom-groups which present themselves after cortical lesions conform, in general, to certain special types, which recur without being closely dependent on the localization of the cerebral injury. These symptom-groups represent, in fact, efforts at the formation of a new equilibrium on the part of a being endowed with consciousness and memory on the one hand, and with a complex brain-mechanism on the other. The principle on which this readjustment goes on in cases of actual cerebral lesion, is analogous to that which is operative in "hysteria."

The points of special interest in my own cases, are as follows:

CASE 1 is that of a young man of 21 who, four years before, had suffered from a continued fever, considered at the time to be typhoid, which confined him to his bed for 13 weeks. In an early stage of this illness, and while the diagnosis was still doubtful, his father went into his room one morning and found him unconscious. Three weeks later, while the illness was at its height, he complained one day of numbness of the hand, and almost immediately afterward became entirely paralyzed on the left side, even to the left eyelid, and swallowed with difficulty. He suffered during this period from severe pain in the head and was thought to have meningitis, but in the course of three or four weeks he could use the arm and leg pretty well, and, before long, all signs of disease seemed to have entirely vanished. It was six months later before indications of cerebral disorder reappeared, and then in the form of attacks of numbness of the left hand, often confined to the index finger and thumb, sometimes associated with twitching, or with irregular movements of the fingers, one after another, sometimes with a greater or less spreading of these feeling and movements to the arm and face. Only six times in all had he lost consciousness, but the numbness of the hand was sometimes preceded by a sense of fullness in the head. The leg was not much involved, but on recovery of consciousness it would feel heavy and helpless. Two or three times he had a blurring of the vision instead of the "numb" feelings, before the severer attacks, and occasionally the forefinger of the right hand would grow slightly numb instead of the left.

Operation was advised, and was done by Dr. J. C. Warren, at the Massachusetts General Hospital, June 3, 1901. A large opening having been made over the "hand-centre," Dr. Warren proceeded to reflect the dura. This was found to be united to the pia by a number of firm adhesions, be-

sides which the two membranes were separated by a dark, soft, velvety layer of tissue suggesting an organized clot, which covered most of the space exposed by the trephine opening (about $2\frac{1}{2}$ inches in diameter) and extended beyond it. The affected area was in fact so extensive that the removal of the whole of it seemed impossible, and it was more for the sake of obtaining a specimen for a microscopic examination than with a view of a cortical excision for therapeutic purposes that a small bit, about 1 cm. in diameter and 1 or 2 mm. in thickness, was snipped out with scissors from the altered pia and cortex. This was done almost at random, since faradization, even with very strong currents, had failed to excite any response. Nevertheless, immediately after the operation, the hand was found to be wholly paralyzed and the sensibility almost wholly abolished. The sensory defect involved the lower part of the forearm but faded rapidly upward. The face also was paralyzed to a considerable degree and the leg very slightly. Trifling thickness of speech, and aphasia to the extent of forgetfulness of names, were present for a time. It is of course possible that these results were referable not wholly to the excision but also to the slight manipulations of the exposed portion of the brain as well as to edema and small hemorrhages as noted by Hitzig (1) in his experiments. But, in either case, the result affords one illustration the more of the fact that in any given area many movements may be more or less represented, and that from a given impression on the cortex certain parts will be far more affected than others; the hand, for example, more than the arm. This fact is well known but its significance is not always appreciated. Many interesting features of this case must be passed over, but I will pause to refer to the fact that in some instances the attacks, even where the most prominent initial symptom was in the hand, were ushered in by a blurring of vision and sometimes a feeling as if the eyes were moving. As regards the further results of the operation, some improvement showed itself before the end of a week, and it was not long before the motion of the hand was regained for the most part, though there was for several years, and perhaps has remained permanently, a trifling diminution in strength and dexterity. The attacks continued for a long time much the same as before as regards frequency, but became less severe and somewhat different in character, the fingers on the ulnar side of the hand sometimes being the more affected, instead of those on the radial side, for example, besides being persistently somewhat paresthetic. The forefinger was not noticed to twitch except once or twice until six months after the operation, though paresthetic attacks were frequent. After a time his condition began to improve in every respect, and a letter received nearly six years subsequently said that he had given up the use of all medicine, that the ill turns were much less frequent, the general health good, and that on the whole he was "quite another man since the operation." Nevertheless, it should be remembered that the lesion remains, so that the improvement, however it may have been brought about, is to be laid to the score of increased cerebral resistance rather than to removal of irritation. Another letter of the present month, written just ten years since the operation, states that the improvement has maintained itself, though he is not perfectly well.

The special interest attaching to this case lies in the fact that, on the one hand, a large and persistent cortical lesion produced highly localized and specialized seizures, of somewhat varying sorts; and, on the other hand, that a trifling injury, of indeterminate localization, consisting in exposure of the cortex, and the snipping out of a small piece, not more than 2 mm. in thickness, induced an extensive group of symptoms corresponding to one of the several definite types, such as is apt to reproduce itself from brain injuries of various sorts, not, it is true, wholly without regard to the seat of the injury, but without close correspondence to it.

The blurring of vision observed in this case was apparently due, in part at least, to a temporary strabismus. It is, however, of interest to note that

the visual deficit was always referred to one side, as so often in migraine.

CASE II is that of a young girl of eleven, who ever since her fourth year had suffered from fits, ushered in by numbness of the right hand and arm, sometimes to be checked by rubbing the affected parts. At the time of my examination the motions of the right hand were somewhat awkward, and lack of development was evident, so that the case was assumed to be one of infantile cerebral disease. During the attacks consciousness was, as a rule, not wholly lost, but the face and leg were frequently involved to a slight degree. Operation was advised, and was done by Dr. Warren, at the Massachusetts General Hospital, on February 25, 1890. The dura was found strongly adherent to the pia over an area the size of a quarter of a dollar. After separation of these adhesions faradic stimulation, even with the strongest currents, failed to excite movements, except at one point, where we were able to introduce stimulation excited twitchings about the mouth similar to those noticed during the seizures. Since it had not been possible to localize the centre for hand movements nothing further was done at this operation. The patient did very well for a time, but after a few months the attacks returned as badly as before or worse. Another operation was therefore attempted but the dura was found still more adherent to the underlying parts and electrical stimulation again failed to excite the cortex. It is noteworthy that although the surface of the brain was considerably torn in the dissection of the dura no paralytic symptoms followed the operation, except slight difficulty in swallowing. The attacks were again relieved for a time, but again returned later, and this time with mental deterioration, which was progressive and necessitated the removal of the patient to an institution for the feeble-minded.

One is tempted to explain the non-occurrence of the paralysis by assuming that the exposed portion of the brain was already damaged, or, rather, that its coefficient of dynamic efficiency was low, in correspondence with the impaired use of the hand. It may well be that this was the case, but it would perhaps involve a straining of this explanation to make it apply to cases such as those reported by Starr and McCosh, where the resection of a large piece of the cortex for focal epilepsy did not excite paralysis at all, but only a moderate disturbance of coordinated motion. It is to be borne in mind in this connection that similar operations upon dogs may fail to excite paralysis, although this is exceptional. (Tonnini.) The case reported by Sachs and Gerster, where even bilateral excision caused only a trifling impairment of function, is interesting in this connection.

CASE III.—The next patient was a man of thirty-three, with an early history of special interest, partly because he had had pulmonary tuberculosis in a mild form; next, because of an injury which may well have been the starting point of his later illness. When a boy of eight or ten years old, namely, he had run while at play, head foremost and with great violence, against the projecting end of a beam, which came in contact with the left side of his head near the vertex. He was knocked senseless by the blow, but seemed after a time to have recovered without permanent injury. Within about two years of this period the first symptoms of his present illness showed themselves, in the form of recurring attacks of "prickly feelings" in the thumb, forefinger and middle finger of the right hand and the adjoining portion of the palm. Sometimes, also, the right side of the face, in the parts adjacent to the angle of the mouth, would be involved, and the right half of the tongue. Occasionally the attacks would begin with paresthesia on the inner surface of the upper arm, about midway between the elbow and the shoulder, and would spread thence both up and down the arm and to the adjacent portion of the chest (area of distribution of nerve of Wrisberg?) and the attacks beginning in this way were the ones most likely to terminate with face and tongue symptoms, and were therefore the most dreaded. With slight

variations in type these attacks recurred at short intervals, rarely a day passing without one or more of them. Indeed, their frequency had gradually increased but the tongue was less often involved than formerly. Occasionally, though rarely, these paresthesias were attended with clonic spasm, or flexor cramp, of the fingers and even the arm, of moderate severity. The first occurrence of this sort was in 1896 and in the three years following it was repeated five times. Twice only, both of the times being on the same day, he had a loss of consciousness, preceded by a severe jerking of the arm, and by a painful feeling as of a series of blows, delivered successively at higher and higher levels from the neighborhood of the hand to near the shoulder. It felt, he said, as if the arm was being chopped off in segments with an axe or by machinery. On two or three occasions, also a temporary embarrassment or even loss of speech occurred, generally in the early morning. The attacks in the hand repeated each other with great accuracy. The first sign would be a stinging sensation in the end of the thumb; this would be followed by a similar feeling at the end of the forefinger; and then by a sensation as of something darting down the length of the forefinger, then along the middle finger and into the radial portion of the palm of the hand. Finally, the face near the mouth would be involved.

My first examination, in August 1898, revealed a very slight paresis of the right side of the face, a slight but definite impairment of cutaneous sensibility over the palmar surface of the thumb and forefinger, as tested by light contact and pricking, and a slight awkwardness in the use of the fingers, as in buttoning the clothes. The sensibility of the right side of the face was affected similarly but to a less degree. There was no considerable gross weakness of the hand, except for a time after each attack.

Although these parasthetic seizures did not incapacitate the patient for work, yet they harassed him greatly, and he readily consented to the idea of an operation, which was, however, not performed until December 15, 1899, on account of the presence earlier of slight tubercular signs in the lungs. By the time of the operation these signs had disappeared and no bacilli of tubercle could be found.

The operation was performed by Dr. J. C. Warren, at the Massachusetts General Hospital. A large trephine opening was first made over the Rolandic convolution, but nothing abnormal was seen until the dura had been reflected, when the pia toward the anterior part of the space was found to be opaque. The opening being enlarged in that direction a tough adhesion of the size of a knitting-needle was discovered, uniting the pia and the dura together. This was excised, together with a small bit of the cortex, Dr. Warren having first assured himself by a careful exploration with the probe that the surface of the brain for some distance around was free from similar lesions. It may be stated here that a subsequent microscopic examination of the excised piece, by Dr. W. F. Whitney, confirmed the view which the appearance of the parts had suggested, that the changes were due to inflammation, not to new-growth.

The recovery from the operation was satisfactory in all respects, the skin-wound healing by first intention.

An intensification of the numbness in the fingers, and of the impairment of tactile sense, and the extension of these signs to the ulnar distribution, which was manifest immediately after the operation, together with an increase of the facial paresis, indicated that the neighborhood sought had been reached, though it cannot be affirmed that the whole lesion was removed. The opacity and edema of the pia, slight as it was, would indeed suggest a wider extension of the cortical irritation.

On the second day following the operation he had a bad attack of numbness, with cramping of the hand, then two days passed without attacks. During the following two weeks, the numbness recurred more frequently than before the operation, but without much cramping, and with a tendency to lessen. The facial paresis soon became less, and a paresthesia of the tongue and gums on the right side, associated with a hesitation in speech, which were all considerable just after the operation, had almost disappeared by the end of the third week.

In the two years which have elapsed since the operation the attacks of numbness have recurred about as before, and there has been in addition an almost continuous paresthesia of moderate degree.

not exclusively limited to the median nerve distribution. The left foot has also become the seat of occasional sensations of similar sort—referred especially to the joints of the toes,¹ and the same feeling has been present in the right side of the neck.

It is worthy of remark, as recalling the observations of some of the cerebral physiologists who found that the tendency of cortical irritation to produce epileptiform spasm could be intensified by gentle stroking of the limb, that this patient has at times noted a recurrence of the numb seizures when the ends of the fingers were rubbed or knocked. Yet, strangely enough, it was not possible to produce this result at will, the admixture of conscious volition seeming to exert a sort of inhibitory effect. Before the operation it was only the end of the thumb which acted in this way as an epileptogenic zone, but since then the same peculiarity has been shared by the ends of some of the fingers.

Cases of "Jacksonian" Epilepsy of various types have been so often reported as to be thoroughly familiar, and the fact is well recognized that one has no right to infer a limitation of the lesion or disease-process to the cortical area corresponding to the "signal symptom." Sharply localized epileptiform outbreaks occur with tumors of considerable size and even in "idiopathic epilepsy," and this occurrence seems to indicate no more than that a certain cell-area is abnormally unstable, whether on account of disease or from an inherent excitability due to the nature of its functions, as in the case of the areas corresponding to the mobile hand- and speech-organs.

In correspondence with this is the interesting fact, well illustrated by the present case, that the irritation due to a given lesion may induce, multiple or alternative results, represented here by the occurrence, now of the thumb-numbness, now of the upper-arm-numbness, as the "signal symptom." The plausible explanation is that the corresponding cortical areas are particularly irritable, so that a discharge may easily start in them with sufficient force to act as a vortex center.

The resemblance of this case to Case I, especially as regards the paralysis after operation, yet with a lesion of far less extent and severity, is also obvious.

CASE IV is that of a boy whom I had the opportunity of watching for a long time before the operation, which was done by Dr. Keen, of Philadelphia, and have had under observation ever since. He had had from early childhood frequent attacks, of short duration, and not always attended with entire loss of consciousness, in which his head would turn to the right and make a rapid series of nodding movements, while the right shoulder would rise and fall rapidly. The right arm was also more or less involved. Severe or general convulsion did not occur. There was no reason to suspect localized disease of the cortex, but the prominence of the shoulder movements suggested the hope that excision of the corresponding part would be of some avail. Localization was carefully done on the skull, and afterwards, successfully, by faradization of the cortex, and the corresponding portion was then excised by Dr. Keen. A temporary weakness of the arm followed, but the epileptic attacks went on much as before, though somewhat changed in character, and all that can be said (which is perhaps a good deal) for the effects of the operation, is that from that time the signs of the disease have been somewhat more manageable by bromides and other treatment.

CASE V is that of a young man of seventeen, of excellent habits and good previous health. His previous history shows nothing that would explain the present symptoms unless that he had a very severe whooping cough when four or five months old, and that having been fond of athletic sports, he had received a number of severe blows on the head, though not such as apparently to cause permanent injury. For the past two years he had grown very rapidly. During the past year he had become gradually aware of prickling sensations in the left hand and fingers, recurring from time to time and lasting about fifteen seconds. During these times the sensibility of the skin would become heightened, so that a rough object would feel still more rough, etc., while at the same time the hand would lose its strength. There had been no impairment of consciousness until three weeks before examination, when he had had two convulsions in one night. Since then the numbness of the hand had become worse, so as to be actually painful, and the fingers would become cramped in a position of extreme extension. The thumb being drawn in upon the palm of the hand. The pain was usually confined to the last two joints of the index and middle fingers and the end of the thumb.

Without entering on further details, I will say that after a thorough bromide treatment, under which the attacks remained absent for a number of months, again recurring, however, at the end of that period, it was decided to operate, in the hope that some cause of local irritation would be found as in some of the other cases.

The operation was done by Dr. Warren in February of the present year, a large skin and bone flap being turned back and the dura incised and reflected. The cortex presented an absolutely normal appearance and nothing more was done than to palpate for underlying tumor or cyst. As a result of this manipulation, or of the simple exposure, a well-marked paresis of the hand came on, with impairment of sensibility in all modes, including the sense of position and the steronostic sense, and, a slight drooping of the left side of the face. These conditions were exactly like those which were reported as following operation in the preceding cases, but less severe, and not more lasting. Only four months have elapsed since the operation was done, and I report the case only for the sake of completeness and the interest of the diagnosis. In fact, however, the feelings in the hand have been much less frequent, thus far, and no severe attacks have occurred. He is on a thorough bromide treatment which it is planned to continue for a long time. The only way in which it would have been possible to differentiate this case, where no gross lesion was present, from those where localized meningitis was found, would have been by the entire absence, before operation, of any trace of permanent impairment of the functions of hand, which in the other cases was present, though to a very trifling extent.

CASE VI.—I wish finally to report the final history of a very interesting case reported by Dr. A. T. Cabot (*Boston Med. and Surg. Jour.*, 1897, I, p. 433) in conjunction with whom I had the opportunity of studying it. The pathological diagnosis, which could not be made with positiveness before the operation, was a large, subcortical cyst, believed after examination, to be of traumatic origin. The original "signal symptom" was a paresthesia of a certain area on the right thigh, but later the very interesting sign showed itself of a paresis or even paralysis of the leg, and sometimes the arm and face, coming on at times as long as fifteen minutes after the initial symptoms had passed away. Loss of consciousness was comparatively rare.

A thorough and continuous draining of the cyst seemed to lead to its filling up and obliteration, and attacks became slight and rare, so that the patient felt able to marry and to engage in active and responsible occupations which he managed for several years. News has, however, recently reached Dr. Cabot that the attacks returned some six months ago, and still more recently that he had suddenly died.

It is noteworthy that the "signal symptom" in this case was, as a rule, a numbness over a portion of the thigh, instead of over the hand or foot, as is the rule, though the lesion was of such large size as necessarily to involve extensive areas. It is also of importance, as illustrating the occurrence of psychical phenomena even with these localized

¹ In Case I, the hand of the side opposite to that usually affected was involved occasionally, even alone.

lesions, that the patient would sometimes jump up and laugh or show odd behavior for a moment as the sensation was first felt. Such acts recall the familiar cases where a dream is initiated by some slight excitation, such as a knock on the door, yet develops in such a way that the noise seems to form the last stage of the process instead of, as in fact, the first. It may be readily conceived that the psychological portion of the attack might, on some subsequent occasion, initiate the process in its turn.

(To be Continued.)

WHAT I HAVE LEARNED FROM ONE HUNDRED AND SIXTY-ONE OPERATIONS FOR THE RELIEF OF SENILE HYPERTROPHY OF THE PROSTATE GLAND.

By ORVILLE HORWITZ, B. S., M. D.,

of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College;
Surgeon to the Philadelphia Hospital, Jefferson Medical College
Hospital and State Hospital for the Insane.

(Continued.)

Prostatectomy.—The operation of prostatectomy is at this time being carefully studied by genito-urinary surgeons throughout the civilized world. I am in accord with Guiteras when he says: "The subject may be considered as still in its infancy." There is much to be learned regarding the safest method to adopt when performing the operation, many important points relating to it are still sub judice, and open to discussion. Some authorities advise that the suprapubic process be selected, others prefer attacking the gland through the perineum, whilst many believe that the safest and best results are obtained by a combined suprapubic cystotomy with a perineal incision. It still remains to be demonstrated whether performing a partial prostatectomy, removing only the obstructing portion of the gland, or a complete resection of the organ, is to be preferred. The latter operation is still on trial. That the dangers attending a complete prostatectomy are many there can be no question. Recovery is always prolonged. Complete removal of the prostate must appeal to anyone as a brilliant, but at the same time a most unsurgical, procedure. To incise the capsule, and then entirely by the sense of touch, violently tear out the entire gland, only leaving the mucous membrane surrounding the urethra, does not appeal to our surgical sense as a rational procedure. After the gland is removed nothing remains but the capsule and the mucous membrane, forming the prostatic urethra, denuded of all the tissue which surrounds it. It is a question as to what becomes of this tube of mucous membrane after the operation which is left free in the capsule. It appears to me most probable that in many instances it undergoes necrosis and is cast off as a slough and discharged with the urine. I have known it to be frequently damaged by the operation; in two instances I have seen the entire prostatic portion of the canal removed with the gland. This is not to be wondered at when we consider how intimately connected the mucous membrane of the prostatic urethra is to the surrounding structure. That a portion of the urethra has been repeatedly resected and on recovery having taken place

the canal remaining functionally satisfactory, is well known. Rollet reports a case of traumatic stricture in which he excised two inches of the urethra; successfully restoring the canal to its normal condition. I have on several occasions performed urethrectomy with the most gratifying results. It is possible, therefore, that by leaving a catheter in situ for a long period of time, after completely removing the prostate gland, that a new urethra forms around the instrument, just as we know it does after the membranous urethra has been excised. That the profession is still at variance as to which is the best operation to perform is shown by the many different methods that are advocated. McGill, Belfield, Fuller, Alexander, Syms, Pyle, Von Dittel, Fryer, Warholm, Nicoll, Guiteras and Tobin recommend a different way of attacking the prostate gland, claiming a more ready access to the organ, others a modification in the technique, asserting that by pursuing the method advocated that the time required for the performance of the operation is thereby minimized, the shock lessened, and the hemorrhage reduced; hence decreasing the mortality. The neophyte having but little experience in prostatic surgery is naturally at a loss to determine which is the best operation to employ.

There is a large number of cases where the prostatic obstruction has been allowed to exist for such a length of time that when they come under the care of the surgeon, the tortuous and narrowed calibre of the prostatic urethra prevents the use of the Bottini incisor, whilst the physical condition of the individual is such as to preclude the resort to so radical a procedure as prostatectomy; these must be treated by a resort to either the establishment of permanent suprapubic drainage, or, in suitable cases, to castration. When it has been determined that prostatectomy is the proper operation the first question that arises is: Shall the gland be removed by a suprapubic incision; through the perineum, or by a combination of both methods? The answer must depend upon the character and size of the growth, its form, and its course. Where there is an interurethral or intercystic pedunculated tumor, a suprapubic cystotomy is the operation to be chosen, when both the lateral and median lobes are equally enlarged and protrude well back into the bladder, the prostate gland is more readily reached by a suprapubic incision, the obstructing portion being removed after the manner suggested by Fuller, a perineal drainage being established as recommended by Belfield.

This operation is likewise indicated if the lateral lobes jut into the bladder, forming multiple tumors about the neck of the viscus, not only elevating the internal urinary outlet, but usually forming two pouches, one above and the other below the projecting gland. An enlargement of the right or left lobe alone or a general enlargement of both lobes is best reached by means of the perineal incision; especially if the tendency of the growth is towards the urethra or rectum, rather than towards the bladder. When the prostatic enlargement is due to an increase of the stromal tissue, and does not impinge upon the bladder, it will be found that if an attempt is made to remove the growth by means of the suprapubic opening that it will be a very difficult and

unsatisfactory operation, usually resulting in the obstructing portion being removed piecemeal, which requires much time for its performance, and is attended with the loss of a large quantity of blood. It is believed for this reason that the gland, in this class of cases, is best reached through the perineum.

My experience coincides with that of Wishard who states: "That cases are not suitable for complete perineal prostatectomy in whom, owing to the prostatic hypertrophy, the posterior urethra has become increased in length to such an extent as to prevent the surgeon from introducing the finger into the perineal wound to reach beyond the growth." The lengthening of the urethra is easily determined by taking the proper measurements by means of a catheter, and making a digital examination of the prostate gland through the rectum.

When attempting to perform a perineal prostatectomy we have our choice of various methods of making the incision; Alexander recommends a median incision, together with a suprapubic opening, so that the prostate gland may be pushed well down into the perineal opening. A lateral incision, beginning at the tip of the coccyx passing to one side of the sphincter ani, and terminating in the perineum has the high endorsement of Von Dittel. A transverse cut extending from one tuberosity to the other is advocated by Warholm; finally a semi-circular flap beginning between the sphincter and tuber ischii, one side crossing the center of the perineum down to a corresponding point on the opposite side from which it began, is suggested by Pyle.

In four operations I have employed the median incision advocated by Alexander and have liked it less each time that it was used. When attempting to remove the lateral lobes the operator is unable to see the field of operation, it being difficult even by touch to determine exactly what structures are being incised. The surgeon is at a great disadvantage from having to work in the dark. The lateral incision of Von Dittel I have never employed; it has many advocates.

In two instances, when removing a prostate gland which had undergone malignant changes, the transverse cut was found to be most satisfactory; the room afforded was ample, the gland could be easily dealt with, and hemorrhage controlled; it has much to commend it. The semi-circular method of Pyle was employed in three cases; it was the most satisfactory of any employed for ordinary cases of perineal prostatectomy. The space employed was ample; the gland could be readily manipulated, and the surgeon can easily observe the entire field of operation after the capsule has been incised and the gland loosened.

Anyone who has frequent occasion to perform perineal prostatectomy will agree that it is often a very difficult procedure; the most important step is that of dividing the capsule of the gland in order to lay it bare, and at the same time loosening the structure sufficiently to permit the gland to be brought into view; the surgeon to do this must necessarily rely entirely upon the sense of touch. Working in the dark, in a deep wound in the per-

ineum, is necessarily unsatisfactory, and is one of the principal objections to this method of procedure. Even after the gland is freed sufficiently to be brought into sight, it is often difficult to separate the lobes from the urethra, without injury to the canal. The rectum has been injured in some cases giving rise to perineo-urethro-rectal fistula, often difficult to cure. I have had this mishap occur to me on two occasions when removing a prostate that had undergone malignant changes, fortunately in both instances the fistulae closed spontaneously. Both patients were invalids for a lengthened period after the operation.

It is generally understood that the power of retaining urine in the bladder depends upon three sets of muscles; two involuntary; the third under the control of the will. The first is the muscular structure surrounding the internal vesical opening of the urethra in the prostate gland and is known as internal prostatic sphincter; this muscular structure has sufficient power to allow from three to four ounces of urine to accumulate in the bladder, when it relaxes and allows the urine to flow into the prostatic urethra, which dilates and assumes a funnel-shape, forming the neck of the bladder.

The onward passage of the urine is then arrested by the second muscle, which is the external prostatic sphincter, it appears to be stronger than the internal sphincter and is capable of retaining the urine until the viscus is well distended: it then relaxes and the retention depends on the contraction of the voluntary fibres of the compressor urethra, which is the third muscle of the series. This explanation of the retention of urine in the bladder seems plausible when the position and action of the various muscular structures concerned are taken into consideration. There must, however, be some other cause of which we yet know nothing, otherwise after a complete prostatectomy, where both the muscular structures connected with the prostatic outlets are extensively resected, dribbling of urine would invariably follow; this, however, is not the case. On several occasions I have known trickling to follow the operation, but it invariably ceased after a few days. In many of my own cases nearly the entire muscular structure composing the internal and external prostatic sphincters were cut away, yet the power of retaining the urine within the bladder was retained.

In two cases when attempting to partially remove the lateral lobes of a hypertrophied prostate, fibrous in character, by means of a perineal incision the entire organ was resected. Both patients died of sepsis, one living for three weeks and the other surviving two weeks after the operation. In neither was any difficulty experienced in retaining the urine.

Out of the eleven cases of suprapubic prostatectomy, in five of which the gland was completely removed, three died. Of the remaining eight, two were lost sight of after leaving the hospital, four were cured, and two were somewhat improved, but had to rely upon a catheter that could be inserted easily, but which did not require to be employed as frequently as before the operations. The two cases which were not cured were greatly benefited. In these patients the prostatic obstruction had existed for a considerable length of time, associated with

long standing chronic cystitis, which had wrought extensive changes in the wall of the organ, with hernial protrusions of the mucous membrane, giving rise to a sacculated condition, so that even if the obstruction had been completely removed the function of the bladder would never have been restored. The condition of these cases seems to warrant the conclusion that if a prostatectomy is to be performed an early operative interference is demanded in cases of prostatic hypertrophy with rapidly increasing symptoms of obstruction.

Out of seven perineal prostatectomies two died of sepsis. Of the five remaining cases two were lost sight of three weeks after they left the hospital. Their condition was most satisfactory when last heard from. Of the remaining cases, two were cured and one improved; in this individual a chronic cystitis had existed for a length of time before operation.

The mortality of perineal prostatectomy is variously estimated from 14.3 per cent. up to 18 per cent. In the Transactions of the American Surgical Association, 1895, there is an article by Dr. J. William White on "The Results of Double Castration in Hypertrophy of the Prostate," in which he places the mortality of perineal prostatectomy at 14.3% and suprapubic at about 7%. If selected cases only are chosen for the operation of perineal prostatectomy and the most recent method resorted to, together with the employment of spinal anesthesia, the mortality will be much less than the stated percentage. The surgeon should always bear in mind that the chances of death are much greater in the perineal operation than they are in the suprapubic. Moreover, after the patient has undergone the nervous shock, pain and prolonged convalescence concomitant on the resection of the prostate, there is a certain proportion of cases that will be unimproved. This is shown by a report of 22 operations by Desnos (*Annals des Mal. des Org. Gen.-Urin.*, 1895), where 15 were cured, 4 not improved, 1 became worse and 2 died.

The high mortality attendant upon excision of the prostate is sometimes due to the fact that a radical operation is undertaken without preliminary preparatory treatment. Much can be gained by continuous catheterism, irrigation of the bladder, the administration of remedies that will have a tendency to render the urine innocuous and produce reconstructive metamorphoses.

Of all the various methods of performing complete prostatectomy, of which I have had the most experience, the safest and most satisfactory is the suprapubic operation by the method suggested by Fuller. It has the advantage of requiring a shorter time for execution than any other. The modification suggested by Guiteras of pushing the prostate up towards the bladder by means of the index finger of the left hand inserted into the rectum while the gland is being enucleated greatly facilitates the removal. My conclusions respecting prostatectomy may be summarized as follows:

1. With the exception of ligation of the internal iliac arteries, prostatectomy is the most dangerous

of any operation that has been recommended for the relief of prostatic obstruction due to hypertrophy.

2. Suprapubic prostatectomy is the safest method, especially if combined with perineal drainage.

3. The best period to select to perform this operation is early, before the break-down of catheter life and serious complications have supervened.

4. Either an atonied or contracted bladder of long standing, associated with chronic cystitis, attended by the formation of sacs, or pouches, are contra-indications for the operation.

5. A partial prostatectomy is indicated in those cases where a valve-like lobe exists, which interferes with urination, or where there is partial hypertrophy of one of the lobes.

6. A complete prostatectomy is indicated where a hypertrophy of the three lobes has taken place, especially if the condition is associated with tumor formation, projecting well back into the bladder, or has given rise to a stenosis of the prostatic urethra.

7. Perineal prostatectomy is best suited to those cases where the enlargement of the lateral lobes has a tendency to grow towards the rectum, or obstruct the urethra.

8. When performing a perineal prostatectomy the semi-circular incisions advocated by Pyle, or the transverse cut of Worholm is the most satisfactory.

9. The removal of a portion of a small, hard, fibrous prostate gland by means of the perineal route is a very difficult operation. There is danger of not only extirpating the entire gland, but the prostatic urethra as well.

Bottini Operation.—Thirty-three patients, between the ages of forty-nine and eighty-one years, were operated on by me by the "Bottini Method." No death resulted. According to Dr. Fredenberg (Berlin), the most recent statistics show that good results can be looked for in 86.63% of cases. Failure in 7.6%; mortality in 4.5%.

For convenience of description the cases that I have treated may be divided into three groups:

First, comprising individuals who were commencing to suffer from the effects of prostatic obstruction, and who required the daily use of the catheter. These were between the ages of forty-nine and sixty-one. Heretofore this class of patients would have been placed upon what is known as the "Palliative Method of Treatment." Of fourteen who submitted to the operation, before the secondary pathological changes that follow prostatic hypertrophy had taken place, all made prompt recovery; the period of convalescence varied from four to eighteen days. When operating on patients at the beginning of prostatic hypertrophy, the gland, as a general rule being but slightly enlarged, a prostatic incision with a smaller blade should be employed than that which is used in more advanced cases. The Bottini operation performed early may be regarded as a radical method of treatment resulting most favorably. It would seem as though the time had passed when the physician is satisfied to advise his patient to use the catheter daily and patiently wait until the obstruction becomes so great and the complications so grave that some radical surgical procedure is necessary to give relief.

Second. The second group of cases comprises

those where the obstructive symptoms have existed for a lengthened time, where the bladder is beginning to be involved, and is in the process of undergoing pathological changes. Catheterism is daily requisite; the physique of the individual being still in good condition. This group is portrayed by eight operations; the individuals being between fifty-nine and sixty-three years of age; the period of convalescence including necessary after-treatment was from two weeks to four months. Of the number operated upon five were cured; two were improved, and one was benefited, so far as residual urine was concerned, which was owing to the bladder being atonied and paralyzed; the catheter was readily inserted, the prostatic spasm having been entirely relieved by the operation. A slight amount of cystitis continued with a persistence of residual urine, rendering the use of the catheter necessary.

To the third group belonged men more advanced in years, their ages ranging between sixty-five and eighty-one years, in whom prostatic hypertrophy had existed for a lengthened period, who had reached what is known as the "Break-down of Catheter Life," whose general health was below par, with atheromatous degeneration of the blood vessels, and polyuria, together with damaged bladder and kidneys, and who had suffered from repeated attacks of retention of urine. A large amount of residual urine existed in each instance. All were in too poor a condition to withstand a capital operation and before the introduction of Bottini's method would have had to rest satisfied with some palliative procedure.

(To be Concluded.)

THE VALUE OF THE COMBINED MEDICAL AND SURGICAL CLINIC TO THE STUDENT.

By ROBERT G. LeCONTE, M. D.,

of Philadelphia

If the student of a few years ago should look at the changes that have taken place in our medical schools, particularly with reference to the teaching of medicine and surgery, he would be struck with the greater number of hours given to the clinical (i. e., bedside) teaching, either in large classes in the amphitheatre or small sections in the wards, and to the lesser position occupied by the didactic lecture. The value of this improvement cannot help but appeal to him, as he will recall how well-grounded he was at graduation on the theory of medicine, and how woefully ignorant of its actual practice. Such was my own experience. I felt on graduating that I had climbed some of the rungs of the ladder of medicine, but twenty-four hours in a large hospital speedily convinced me that I was still groping on the ground, and that my small store of theoretical knowledge was practically useless. The present system of teaching is a distinct advance in making the medical course more practical, but cannot our methods be still further improved by combining the medical and surgical clinics in such diseases as have a medical and surgical aspect? At present it is the general custom to devote two consecutive hours to clinical study, the first to medical, the second to surgical teaching, but the professor of medi-

cine does not arrange his lecture with a view to the surgical clinic, nor does the surgeon inquire into the subjects that the instructor in medicine is illustrating. Each has his own wards, his own cases, and chooses such material as seems best to him, not knowing or caring what his colleague will teach, and so keeps the two branches of the science as separate as noon is from midnight, forgetting the harmony of a dawn and a twilight.

There are many diseased conditions which should properly, at first, undergo medical treatment, but which later come under the care of the surgeon; and there are also forms of the same disease which should from the beginning be either medical or surgical. How is the student to differentiate these conditions, or know when a disease ceases to be medical and becomes surgical, unless he is given a clear and definite continuous picture, by seeing the medical treatment of the case in question followed by the surgical treatment that would be applicable. As instances of what I mean, let me mention some of the diseases and conditions in which such a combined method of teaching would be of great value to the student: Diseases of the pleura, hydro- and pyothorax. Diseases of the lung, abscess, gangrene, localized tubercular deposits. Diseases of the pericardium. Ulcer and carcinoma of the stomach. Diseases of the intestine, appendicitis, malignant disease, intussusception, typhoid fever and perforation. Abscess, cirrhosis and hydatid disease of the liver. Empyema of the gall-bladder, gallstones. Diseases of the pancreas, of the spleen, of the lymphatics, of arteries (aneurism), of veins, of the spinal cord and the resulting atrophies and deformities. Diseases of the thyroid gland, Graves' disease, and tumors. Cranial neuralgias with tic douloureux. Epilepsy, idiopathic, Jacksonian and traumatic. Hemorrhagic and embolic apoplexy contrasted with extra- and intradural hemorrhage. Abdominal enlargements the result of ascites, tuberculous peritonitis, cysts of the ovary, pancreas, kidney, etc.

Each disease which lends itself to a grouping of this character should be carried from its incipency to its termination, and the student should have a picture which he would not forget, and one which no single text-book could furnish him. I believe in a few isolated cases this system of teaching has been tried in Philadelphia. Agnew and Pepper, White and Bruen, White and Guiteras have given combined clinics on empyema, and Agnew and Wood, and White and Wood on brain tumor, but I know of no school or hospital that has attempted to follow it out at all systematically. It would, therefore, seem expedient to relate the experience of Dr. Frederick A. Packard and myself, who tried this method at the Pennsylvania Hospital last fall.

We were associates on the wards of the hospital during October and November, 1900, and gave eight clinics in the two months. We arranged seven combined lectures, but at the last moment one case refused further treatment and left the institution, so that only six combined clinics were given. These were on gangrene of the lung, cirrhosis of the liver, epilepsy, Graves' disease and goitre, diseases of the lymphatics, and diseases of the pleura. The lectures varied from an hour and three-quarters to possibly two hours and a quarter in length. An attempt was

made to trace these diseases from their incipency to their various terminations. The pathology was freely discussed and illustrated with such specimens as could be secured. The patients themselves were examined before the students and the diagnoses made. They were then removed from the clinic and anesthetized, while the various surgical procedures were discussed and then illustrated on the individual case. At some time later the results of our treatment were shown and discussed, whether the case terminated favorably or fatally.

At the risk of being thought too explicit, let me describe in greater detail our first and second clinic. The first lecture was on gangrene of the lung. The patient's chest and also the hands of the operator were carefully disinfected before entering the amphitheatre. The clinical history of the patient was carefully gone into and the physical signs demonstrated with the hands of the physician covered with sterile rubber gloves. The causes and pathology of gangrenous abscess of the lung were spoken of, and the statistics of medical treatment given, while the patient was removed from the room, again cleaned, and a sterile dressing reapplied. As ether was being administered the surgery of the lung was reviewed, its dangers and complications, and the statistical results of operation. The various methods of operating were detailed and the course to be pursued in this case was fully explained. The operation was then performed and the gangrenous cavity opened. The immediate and the probable after treatment were given. One week later he was again shown to the class and his condition discussed. Later, when the patient died from progressive septic absorption, the post-mortem findings were shown and explained.

Two cases of cirrhosis of the liver were the text for the next lecture. The same antiseptic precautions were observed in the preparation of the patients. The clinical histories of the patients were given, and the causes, varieties, medical treatment and statistics detailed. The physical signs present were also demonstrated. The theory of the operative treatment was then discussed and the statistics of operation given, and also our reasons for believing these cases amenable to surgical treatment. The operative technique was then described and the patients operated upon. One of the patients died in four days. At the next lecture the death was reported, the probable causes stated, and our belief that we were in error in administering ether as an anesthetic. Two months later the second patient died and the post-mortem findings were shown to the class, and the causes of death explained.

Such was the method pursued, and the attendance was as follows: At the opening clinic less than forty students were present; at the second about a hundred, and thereafter 150 or 160 would probably represent the average attendance. Neither Dr. Packard nor myself hold positions in medical schools, so the personal element did not influence the attendance, and we may fairly attribute the increase alone to the system pursued. Several students told me that these two hours saved them days of reading, and that the mental picture retained was worth volumes of type. Two physicians also told me it was their custom to rise at six o'clock on our clinic days in order that they might save the two hours

to hear our lecture. I trust you will understand that my quoting such remarks is not done in a vain glorious spirit, for I know full well that my qualifications as a surgical teacher are extremely limited, but I wish to emphasize the fact that with this system our lectures proved very valuable to the students, although the surgical instruction was possibly of an inferior nature.

The drawbacks to such a system are (1) the material at your disposal will not always lend itself to this method of instruction, and (2) the increase of time given by the instructors, for it is expedient that both teachers be present during the whole of the lecture, the surgeon to know thoroughly the medical status of the case he is about to operate upon, and the physician to see the advantages or disadvantages that result from the operation. To the first objection, of course, there is no answer, for if you have not the material you cannot arrange the lecture. But to the second objection I would say, that an instructor who cannot afford an extra hour for the purpose of saving hours of work to each individual student, is of little value as a teacher, no matter how prominent his name may be in the profession.

The benefits derived from such a system seem threefold, (1) to the student, (2) to the patient who has the advantages of the thoughts of two minds instead of one, and (3) to the instructors, for it cultivates in them qualities of the highest value in the practice of medicine.

A CASE OF ABDOMINAL PREGNANCY.

By AUGUSTUS C. BEHLE,
of Salt Lake City.

It is through the courtesy of Dr. S. H. Pinkerton that I am able to exhibit this specimen to you this evening. I will give you a brief history of the case.

Mrs. N—, aged 28; general health good, was married eight years ago. Seven years ago she thought she was pregnant as she had missed three menstrual periods. At the time of her third menstrual period she had a severe pain in the abdomen. She fainted and was then sick in bed for over a month. Her menstrual period then became re-established and continued fairly regular until March, 1900, when she began to notice an absence of her usual menstrual flow. She thought she might be pregnant and consulted a physician who informed her that he thought she was in the family way. Some of the symptoms of pregnancy were present—her breasts began to enlarge and there was some nausea. In June 1900, she began to flow, the flow being slight. There was no clots or membranes passed. This flow lasted about two days and then ceased. Milk was noticed in the breasts in September, the breasts becoming quite full so that there was oozing from them. Her abdomen continued to enlarge. Fetal movements were noted in July. The patient had a fall in October, which started some pains in the abdomen and it was supposed that labor was approaching, but these pains subsided as also did the fetal movements; the secretion of milk had dried up. In January of this year she began to flow and also in February and March. Peculiar pains throughout her abdomen had been present during her whole pregnancy which made her very miserable at times. She considered those pains as the necessary accompaniment of pregnancy. What she had considered fetal movements having ceased, her menstrual flow being re-established and her milk drying up caused her to decide that something was wrong. She came to this city on April 2, 1901, placing herself in the hands of Dr. S. H. Pinkerton, who sent her to St. Mark's Hospital. On April 3, 1901, she

*Reported before the Salt Lake County Medical Society, April 5, 1901.

was examined by Drs. Pinkerton, Worthington and Landenberger, under ether anesthesia. I was asked to examine the patient on April 4th, and found the following conditions: Patient healthy, very well nourished and somewhat browned by exposure to sunlight. She was of medium stature. The areola around the nipple was well marked although there was no pigmentation. The breasts were somewhat flaccid. No colostrum could be expressed from the nipple. The abdomen was uniformly enlarged. The linea alba was not pigmented. Striae were found all over the abdomen and on the side. A tumor was noted which extended a hand's breadth above the umbilicus. It was elastic, semi-solid and non fluctuating. A hard globular mass was made out in the right iliac fossa which was smooth with the exception of a slight depression at one side. Above the umbilicus and toward the left an irregular mass resembling fetal limbs was palpated. The balance of the tumor seemed somewhat vague and difficult to outline. Careful auscultation over the whole abdomen failed to elicit fetal heart sounds or the placental souffle. Vaginal exploration demonstrated the vaginal walls smooth and soft; two fingers could be passed into the vagina with difficulty because of a resistant perineum. The cervix was soft, round and not shortened. The fundus could not be outlined definitely. Rectal examination called attention to a small pseudo-fluctuating body about the size of an English walnut in the cul-de-sac of Douglas. This was sensitive to pressure and recognized as an ovary. A diagnosis of ectopic gestation was made with a probable death of the fetus. The position of the child towards the abright iliac fossa; the dorsum of the child towards the abdominal wall and to the right; the extremities to the left. As no placental souffle could be heard an immediate operation was advised. It was performed by Dr. Pinkerton on April 6, 1901. A median incision was made in the linea alba which was afterwards extended to about 4 Cm. above the umbilicus. A large sac was found with some adhesions to the great omentum. An incision was made through the sac which passed through part of the placenta. The knee of the fetus was then felt; the head somewhat extended and lying in the right iliac fossa, the dorsum toward the right. The cord was severed and the child was delivered. The fetus showed slight signs of maceration. About a pint of thick amniotic fluid was in the sac. Adhesions were now carefully separated, severed and tied thereby gradually freeing the sac from its attachments and permitting of its removal. Some large blood vessels were encountered, catgut being used to tie them off. Very little blood was lost. The uterus was found pushed to the left side, the right ovary being in Douglas cul-de-sac. A well marked corpus luteum was found in this ovary. The right tube seemed normal with the exception of its end being firmly occluded. The left tube and ovary could not be found. The uterus was about the size that you would expect to find in a multiparous non-pregnant woman. It was not deemed wise to do a hysterectomy. The sac was very firmly attached to the uterus at the position of the left cornua and to the pelvis on that side. The attachments of the round ligament to the uterus could be noticed in front of the sac. I have not been able to find the left tube and ovary by a macroscopical examination and have not had time to cut microscopical sections from the sac, but hope to be able to do so as I think they are incorporated in the sac. The placenta was fairly large and attached to the anterior part of the sac as it lay in the abdomen. The abdominal wound was closed with silk worm gut. Patient withstood the shock of the operation very well; her temperature reaching its highest point 100.4° Fahrenheit at 3 P. M. the day following the operation. The patient at the present time is in a very satisfactory condition. The foetus is a male child, very large, weighing 6½ pounds. The child is plump and well developed, no deformity being noticed. One hand is quite puffed and macerated. There is also some maceration of the leg and back. The child measures 53 Cm in length; around the hips it measures 23 Cm; around the shoulders it measures 43 Cm; around the head (forehead occiput) 35½ Cm. The sole of the foot measures 8 Cm.

(The patient made an uneventful recovery and at the present time, May 29, 1901, has regained her former health).

SPECIALISM AND SOME OF ITS RELATIONS TO THE GENERAL PRACTICE OF MEDICINE.

By HENRY WALLACE, M. D.,

of Brooklyn, N. Y.

Assistant Surgeon to St. Johns Hospital, Brooklyn, and Surgeon to Department of Diseases of the Throat and Nose, Polhemus Clinic.

The subject of specialism and its relations to the general practice of medicine and surgery is becoming more and more a matter for deep and earnest thought.

As the field of medicine broadens, both as a result of experience in practice and the fruition of laboratory research, so to every conscientious worker in the profession must come the thought sooner or later: "How is it possible for me to keep up to date in all departments, and should I become a specialist?"

In years gone by, when the general practitioner was more or less able to keep pace with the advances in these special lines, the subject did not command the attention that it does to-day, and with good reason.

To be an all-round good man in those days was a reputation much easier to hold then than it is now. This is essentially an age of specialists, and rightly so, from the standpoint that no man can be an expert in all departments.

The great mistake at the present time is that there is a marked tendency for a man to enter a specialty too early in his career.

A four years' course in a medical college, a year or two as interne in a hospital, with possibly a few weeks spent at a post-graduate school, and the young man starts on his career as a specialist.

He then obtains a clinic in some dispensary, he attends the meetings of the section of his local society which is devoted to his specialty, and waits for a private practice.

The result of all this honest work is that, although he becomes more and more proficient in his specialty, he becomes narrower-minded as regards medicine in its broader sense.

The specialist of to-day should be the product of a natural development, not of a forced growth.

The true method of development comes through years of general training in the broader fields of medicine and surgery, during which time the individual finds a line of work which interests him the most, and for which he is best fitted from many standpoints.

What is the result of this form of development? A man who has the broadening influences of several years' work in the larger field is given an opportunity to discover a branch for which he is specially fitted and which he cannot obtain in any other way.

If, in his general training, he has had especial opportunities of a surgical nature, and he is fond of it, in all probability he will be most interested in a specialty where his surgical training will be of the utmost value to him.

He will then look at his special cases with a broader range of vision and handle them with a corresponding skill borne of this experience.

The average man enters the profession of medicine with the object first and foremost of earning a living.

The natural history of this man's first few years will necessarily be to do everything that comes to him which he can conscientiously handle.

It may be that it is during these early years, though not always, that he sees where his deepest interests lie in the broad field of the profession.

On the contrary, it may be, and very often is, the case, that in the struggle for existence and recognition not only by the public, but by the profession, that he has not the time to discover his natural bent, and if he does he many not find the opportunities for its development.

Then there is a class of men who have been engaged for years in the practice of their profession, and it is not until after several years' experience that they find they have by opportunity and aptitude fitted themselves for some particular line of professional work.

The medical schools of to-day are certainly making advances in the right direction by giving their students a better insight into the specialties than ever before.

The well trained practitioner should be able to examine and in a general way at least make a diagnosis of many of the special conditions and know his limits in the case.

How often the throat and nose specialist will have cases come to him with the statement that they have catarrh, and were told by their family physician to wash out the nose with a solution of common salt in water or to get an atomizer.

When asked whether the physician had made an examination of the nasal cavities, they frequently answer in the negative, and that they were simply told they had catarrh and that simple attention to cleanliness would relieve them of their trouble.

This is all very true so far as it goes, but how often we find that catarrh is due to some condition requiring surgical interference.

Not only this, but the laryngologist of the highest type views his case not only through his own particular spectacles, but with the eyes of the well-trained physician, who can look upon the case broadly and sets to work to relieve it not only by local treatment, but by remedying defects of hygiene, treating constitutional dyscrasias, and general conditions which might cause or aggravate the local disease.

Many disorders of the nasal and laryngeal mucous membranes are due not nearly so much to local causes as to disorders of the gastro-intestinal tract.

To-day better than ever before the young graduate understands that every cough is not due to pulmonary disease, but may be caused by an elongated uvula.

Some months ago I remember treating a case of apparently intractable cough which had been under the care of a general practitioner for a considerable length of time.

He had been given the usual cough remedies without benefit. This case was perfectly relieved in a very short space of time by suitable treatment directed to a much congested and edematous turbinate body.

I have another case in mind where a patient was told that he had hay-fever and was advised to go to the White Mountains for its relief. He did so, and

on his return, as he was no better, it was suggested that he have his nose examined.

He did so and was very much surprised when told that he was suffering from tertiary nasal syphilis which had gone so far as to have almost destroyed the nasal mucous membrane and already to have caused a large perforation of the septum.

It is in such a case as this that the average young practitioner of to-day is ahead of some of the older graduates.

He has learned to make a local examination and in a general way at least to make a diagnosis and to decide whether the case in question is one requiring the attention of a specialist.

As in the case just referred to, the simplest kind of an examination would have shown that the trouble was of a very different nature from hay-fever, which disease he would surely know could not produce a septal perforation.

Such handling of the case would probably have saved months of suffering and irreparable destruction of tissue.

So much from the standpoint of the laryngologist.

These general statements may be challenged, and justly so, as not applying with equal force to all of the special departments of medicine and surgery.

I am free to admit that there are at least two exceptions to my general proposition that the specialist to be thoroughly equipped for his work must have a general medical or surgical training.

I refer to ophthalmology and otology. In former years much more frequently than at the present time these two went hand in hand. This association was, of course, without logical foundation, and we are now accustomed to see the specialist confine himself to one or the other of these two departments.

In *neurology*, however, the broadest and most thorough knowledge of the anatomy and physiology of the entire body, combined with a thorough training in general medicine, is essential to success.

No branch of medicine requires such a thorough groundwork on which to build as this. The nervous system, with its complex anatomy and physiology, its intimate relation to every function of the economy, not to mention its tremendous literature, especially in foreign tongues, all contribute to make this line of study dependent on the most extensive and thorough training in medicine.

As to gynecology, the statement may be made that a man *cannot* become a successful gynecologist at the present time without a broad experience as a general practitioner.

The trained gynecologist must be able not only to recognize conditions amenable to local and operative treatment, but to accomplish much by his ability to recognize and treat disorders of the various systems of the body bearing a close relationship to the pelvic organs.

The day of the office gynecologist is past. Women do not have to submit to days and weeks and even months of local treatment, for we realize now how much more can be done by immediate surgical treatment and within a comparatively short space of time.

The gynecologist of to-day must be a skillful surgeon. He must keep in touch with all the advances

in the technique of general surgery that he may apply them to his own work.

The field of the gynecologist has changed in the last decade. Up to that time a large proportion of his work was in the line of plastic surgery of the cervix and perineum.

To-day he sees fewer of these cases in proportion to those demanding an abdominal or vaginal incision.

This may be explained very logically by the fact that there are now more men competent to do this work, but also by the fact that the student of to-day is better instructed in obstetrics, and in the operation for the immediate repair of perineal lacerations.

A few years ago the student saw possibly a few cases of immediate perineorrhaphy during his maternity course. Not only has he this experience at the present day, but, thanks to modern methods of instruction, he is enabled to obtain an excellent idea of the technique of this operation by class-room demonstration. (I refer to Dickinson's plastic cast method).

In former days a man could hold an enviable reputation as a gynecologist on the strength of his ability to make a diagnosis, to institute local treatment, and to perform plastic operations.

At the present time, the worker in this line must be a surgeon of skill and experience in the much larger field included in the term "abdominal surgery."

And so we might go through a longer list of the so-called specialties, and we will find that the same general principle holds true.

The subject of the relation of the specialist to the general practitioner from the more personal standpoint is one upon which much could be said.

It almost appears at times that some practitioners have a feeling that if they send a case to a specialist they are liable to lose their hold upon it. Far from this being the case, the patient of average intelligence is very liable sooner or later to go to some specialist at the suggestion of a friend.

Here the physician is certainly much more liable to lose his patient than if he had referred the case himself to the specialist and conferred with him in regard to it.

It is possible in some instances that the practitioner fears that he may lose his patient by recommending some one else by apparently acknowledging that he himself is incompetent.

This is most certainly not the case, for the public is intelligent enough at the present time to realize the fact that no physician, however well informed, can be as competent as one especially trained in any given branch.

Not infrequently the specialist is criticized by the practitioner, who has referred him a case, because he is apparently going beyond his proper limits and not confining himself to the purely local treatment of the case.

In such an instance as this, or where it is not desirable for any reason that the specialist should have the entire handling of the case, and as it were taking it entirely out of the physician's hands, the specialist is competent to, and should, consult with the physician as to a line of general treatment and the particular indications for it in the case in question.

It has been said that a man cannot, and should

not, practice a specialty and at the same time be engaged in a general practice.

There are few men who, although desirous of becoming specialists, are able to wait for a special practice.

They are obliged to attend to a general practice to meet expenses, for it takes a longer time to develop a special practice than a general one.

On the other hand, it is very possible that after some years spent in general practice, though with a growing special one, it may be advisable for him to gradually diminish the extent of, or even discontinue his general work and devote all his time and energies to his specialty.

It is perfectly proper and possible then for a medical man not only to be a pure specialist, but to practice a specialty while attending to a general practice.

That in the latter capacity he deserves the respect and support of his colleagues, although he is not a specialist in the strictest meaning of the word.

Preliminary Program of Papers to be Read at the Meeting of the American Neurological Association, to be held in Boston, June 19, 20 and 21, 1901.—(1) Chorea with Embolism of the Central Artery of the Retina with short Review of the Embolic Theory of Chorea. By Dr. H. M. Thomas, of Baltimore. (2) The Course, Prognosis and Treatment of Hysteria. By Dr. Theodore Diller, of Pittsburgh. (3) A Case of Cerebral Hemiatrophy with Hemiplegia and Aphasia, in an adult. By Dr. W. L. Worcester, of Hathorne, Mass. (4) Report of a Case of Brain Tumor, Operation, Recovery. By Dr. Wm. M. VOL. VII, No. 25

JUNE 22, 1901

\$3.00 PER ANNUM

A Contribution to the Etiology of Epidemic Cerebro-Spinal Meningitis.—The April number of the *Journal of Hygiene* contains a valuable contribution to the Etiology of Epidemic Cerebro-spinal Meningitis, by Dr. W. J. Buchanan. In this study especial attention is called to the part played by dust in the causation of this disease. The fact that cerebro-spinal fever is prevalent in India shows that the statement of Hirsch, made in 1886, that the southern distribution of cerebro-spinal meningitis is limited by the thirtieth degree of North latitude does not hold good. Indeed, not only is the disease prevalent in India, in Khartoum, in the Ashanti field force, but in the West Indies. Dr. Buchanan has studied carefully the three epidemics which took place in the Central Prison, Bhagalpur, in Bengal, from 1897 to 1900. There were 47 cases recorded in irregular succession, and this writer divides them into three separate outbreaks. No new facts were obtained which throw any light on the incubation period of the disease. The experience of the outbreak at Omdurnam in 1898 and 1899 show that in some cases it may be very short, from 52 to 76 hours. The prognosis is usually bad, the rate of fatality being very high. Relapses were not uncommon, and in some cases there were short intervals of complete cessation of all activity of the disease. Lulls and temporary improvements were not at all rare. For a favorable prognosis, Buchanan states that the following symptoms are important: The tongue becoming clean; the disappearance of Kernig's sign, and most favorable of all, a prolonged and quiet sleep. This writer believes that Kernig's sign is an invaluable aid to diagnosis. Buchanan's conclusions are of especial interest. He mentions the fact that what is called cerebro-spinal fever in India is identical with epidemic cerebro-spinal meningitis, and this identity is established not only by finding the diplococcus intracellularis meningitidis in the Indian cases, but by the clinical and epidemic aspects of the various outbreaks which he has studied. He is convinced that there is very much evidence to connect the disease with dust, either wind-borne or accumulated upon roofs or evolved in the various processes of grain cleaning. In the Bahagpular outbreaks no evidence was obtained that

pointed to direct contagion, and in no instance were those in attendance upon the sick attacked. The disease was not associated with any prevalence of pneumonia or influenza. Strangely enough, the disease could not be traced to any infection outside of the jail. The first cases in all three outbreaks were in persons who had been inmates of the institution from six weeks to a year. In certain wards there were larger numbers of cases than in others, but there was no direct connection between the cases in these wards nor between the different wards, and often cases in the same ward developed at long and irregular intervals. It was found that in only three cases out of the 47 studied were the patients not exposed to forms of labor in which dust was plentiful. The writer states that this fact is difficult of explanation, unless we believe that dust either renders men more susceptible, or, as is more probable, that it is the actual vehicle of the specific germ of the disease.

The Development of Filaria Nocturna.—The two common species of *Culex* found in St. Lucia are *Culex fatigans* and *Culex teniatus*. Low (*British Medical Journal*, June 1, 1901) has studied the development of the filaria nocturna in these mosquitoes. The insects were allowed to bite a patient suffering from filariasis. At the end of from twelve to twenty-four hours after feeding many actively-moving filaria embryos are seen in the thoracic muscles of *Culex teniatus*. But these embryos develop very slowly, and after reaching a stage in which the alimentary canal is differentiated, an evolution requiring between seven and nine days, the embryos begin to degenerate so that they never reach maturity, and, therefore, never pass to the proboscis of their host. At fourteen days all the embryos have disappeared, only small, imperfectly-developed ones remaining. It is very fortunate that the *Culex teniatus* is not an efficient host for filaria nocturna, because the insect is very bloodthirsty and feeds by day as well as by night.

On the other hand, *Culex fatigans* is comparatively rare in St. Lucia and feeds at night only. In this insect the filaria embryos rapidly reach maturity, so that in eleven and one-half days the meta-

morphosis is complete and mature forms may be seen in the head, neck and proboscis of the mosquito. In St. Lucia, therefore, filariasis is propagated by the bites of *Culex fatigans*.

Manson, working in Amoy, determined the cycle of development of *filaria nocturna* to be eight days. Low, who studied the subject in St. Lucia in March, thinks that if his experiments had been made in the hot weather the complete metamorphosis might have taken place within the time noted by Manson.

Strong (*Circulars on Tropical Diseases*, No. 1, Chief Surgeon's Office, Division of the Philippines) has met with a case of filariasis in Iloilo. The embryos began to appear in the patient's blood in small numbers at six o'clock and were most numerous at midnight. The patient had lymphatic swellings in the right groin and irregular fever. It is not at all impossible, now that so many Americans are coming from the Philippines, that filariasis may become domesticated in the Southern portions of the United States. Low shows that the *filaria* will develop in the body of the mosquito when the atmospheric temperature is comparatively low, although development is slower under such conditions. According to the Division of Entomology of the Department of Agriculture (*Bulletin No. 4—N. S.*) *Culex fatigans* is not included in the list of mosquitoes of the United States. There are, however, several varieties of *Anopheles* within our borders which may prove to be efficient hosts of the *filaria* larva.

The New President of the American Medical Association.—Dr. John A. Wyeth, of New York, is eminently fitted for the new honor which has been conferred upon him by the only representative and really national medical association of America. He is himself to be congratulated, and the American Medical Association is to be congratulated still more. Dr. Wyeth, it is needless to say, represents the type of professional men from whom Presidents should be made. He has attained well deserved distinction, not only as a practical surgeon, but also as a teacher and an author. In the latter class, indeed, his text-book on surgery entitles him to stand in the first rank. It is a matter of especially good augury, we think, that the association not only chose a President from New York, but also selected a meeting place in that state. Saratoga is a delightful resort, and as the American Medical Association has to distribute its meetings over the length and breadth of the land, it might as well pick out the best spots. But the best feature, perhaps, about this selection is that it will tend to re-establish the *entente cordiale* between the American Medical Association and some members of the profession in the Empire State who have felt that they had a grievance against that body. This consummation is devoutly

to be wished. Perhaps now that the Association for several years has honored some of our most esteemed surgeons, it will in the not distant future let the lightning of its favor strike some equally esteemed medical man.

The Pennsylvania Epileptic Hospital and Colony Farm.—It is hardly to the credit of the great State of Pennsylvania that the only institution (with the exception of a small Home), which aims to give proper care to epileptics within her boundaries, is forced to rely almost entirely upon private charity. The Pennsylvania Epileptic Hospital, at Oakbourne, near West Chester, is striving successfully to solve the problem presented by the needs of the epileptic. In a circular just issued it announces its plan of treatment. This consists of work, occupation, out-door life, and a blessed freedom from that ennui of existence which is so often forced upon the epileptic sufferer. The men work on the farm during the summer. They cultivate the land, care for the cattle and poultry, make roads, and keep the grounds, hedges, fences and buildings in repair. In the winter they do shoemaking, carpentering, brushmaking, cane-seating, etc. The women do housework, assist in cooking and laundry work, and in the summer do light work in the garden, cultivating flowers and picking vegetables. The circular from which we quote says farther that statistics show that with regular diet, steady employment and an out-door life, the number and violence of the epileptic attacks diminish greatly. Toward the support of this most beneficent (and partly self-supporting) work the State this year appropriated only \$2500.00. It is greatly to be hoped that public bounty, as well as private charity, will flow in large measure to the support of this colony farm. No other institution in the State appeals more strongly to the sympathy of mankind, while none of the greater charities has been more neglected in Pennsylvania than the one which has for its object the rational and humane care of the epileptic.

Smallpox in the United States.—Up to the time of issue of the latest number of the *Public Health Reports*, there were reported to the United States Marine Hospital Service a grand total of 28,413 cases of smallpox for the United States. The period covered was from December 28, 1900, to June 14, 1901. For the corresponding period one year before only 12,092 cases were reported. Thus it appears that smallpox has increased very greatly in its frequency, being more than twice as prevalent as last year. But the mortality tables show a strikingly different result. For last year there were reported 1,642 deaths, while for this year, although the disease is more than twice as prevalent, the number

of deaths has been only 486. In other words, last year there were about 5% of deaths, while this year so far there have been but $1\frac{1}{2}$ % of deaths. For statistical purposes these reports may not be altogether reliable, not so much from lack of accuracy as from want of fulness. We very much doubt whether all the cases that actually occur in remote and rural districts are reported. This must be so especially of mild cases, for many of these may escape detection. This fact only tends, however, to make it probable that the death rate in reality is even lower than it appears on paper. Highly malignant cases and fatal cases are naturally much more likely to be discovered and reported, hence we do not think it likely that the percentage is too low, but rather the reverse. To what the low mortality of modern smallpox is due, we cannot say. It is an interesting subject for debate and investigation, and we wish some competent observer and statistician would undertake to elucidate it. We respectfully refer it also to the anti-vaccinationists.

The Medical Profession of California and the Plague.—Since there have been, during the course of the plague epidemic in San Francisco, so much misunderstanding and confusion in regard to the various aspects of the situation, an authoritative statement has long been desired. We believe the following statement contained in a letter from a well-informed physician of San Francisco, to be fair and to give to the eastern members of the profession a clear idea of the situation, in so far as the medical aspects are concerned. Unfortunately, the purely scientific question was converted, in large part, into a political and commercial one, to the great detriment of the solution of the hygienic problem concerned.

The diagnosis of plague was first made in the spring of 1900 by the City Bacteriologist, Dr. Kellogg, and the Surgeon of the Marine Hospital Service stationed in Angel Island, Dr. Kinyoun. There is some indirect evidence that similar cases had occurred before, but no pathological evidence lies at hand. Other cases occurred, and upon doubt being thrown upon the diagnosis, other local scientists were engaged in the study of the condition. The cases, some or all of them, were studied by the following pathologists and bacteriologists: Dr. Kellogg, the city bacteriologist; Dr. J. J. Kinyoun, Surgeon of the Marine Hospital Service; Dr. Ophuets, Professor of Pathology and Bacteriology in Cooper Medical College; Dr. Ryfkogle, Instructor in Bacteriology in the University of California; and Dr. Pillsbury, Professor of Pathology and Bacteriology in the College of Physicians and Surgeons. These men, all trained in special work of the kind, pronounced the disease in question to be plague.

A portion of the profession disputed the diagnosis despite the authority and the scientific study of the men mentioned. The opposition to the diagnosis was led largely by three medical men, all of whom hold professorial chairs in San Francisco, and wield great influence in shaping public opinion in California. One of these medical men had himself failed to find the plague bacillus, and afterwards was not willing to acknowledge his error; the other two are not bacteriologists, and based their criticism and opposition upon their mere personal opinions. The whole profession, while divided, was, in the majority, inclined to the belief that the disease was plague. The State Medical Society passed a resolution expressing its conviction that the disease was plague. Cultures were sent to many eastern bacteriologists, and in all instances the replies were in the affirmative. And, lastly, the special Plague Commission again definitely determined that the disease was plague.

The methods employed by the local experts for the positive diagnosis were the same as those worked out by Yersin, Haffkine and the various plague commissions sent by European governments to Asia. This touches the most signal fact of the whole situation, to wit.: that methods unreservedly accepted as reliable and conclusive by the whole scientific world, and by every government which has had experience, were rejected by a portion of the profession of San Francisco. The diagnosis of plague in the beginnings of an epidemic, has in modern times been made in no other way than it was made in San Francisco. Had a report identical with that of the local scientists in San Francisco, been handed in to any European government or to that of their colonies, it would have been unreservedly accepted by the government, the medical profession, the commercial interests, and the public at large. In San Francisco alone has the modern scientific diagnosis of plague been rejected by an influential portion of the medical profession and the public.

The City Board of Health accepted the diagnosis from the first, and has continued to stand by the diagnosis. Though actuated by the best of motives, the Board nevertheless erred in some of its public acts. This was so especially in its establishing a quarantine against the section of the city known as Chinatown. This quarantine was declared illegal and directed to be removed by the courts in an opinion by Judge Morrow, who is reported to have declared from the bench that there was no plague in San Francisco. The quarantine was, in the light of our knowledge of plague, an error. Into this error the local Board was led partly by the conviction that on account of the numerous and un-

known underground passages undermining the section known as Chinatown, other measures could not succeed. Upon the failure of the disease to spread after the quarantine was raised, the public lost confidence in the diagnosis, and it then became impossible for the city Board of Health to procure the funds necessary for the adequate management of the situation. The city Board of Health, however, has maintained the diagnosis, and has never expressed a contrary opinion to the public.

The State Board of Health had not gone on record in the matter. It is generally supposed to be opposed to the diagnosis, but there is no official record of the fact. The Board at the outset was supposed to have been inclined to confirm the diagnosis; but by means of new appointments the personnel of the Board was so altered, that the unexpressed negative opinion has become predominant.

Our correspondent insists upon it that the situation in San Francisco has not been altered in the least by the report of the Plague Commission. He says that the portion of the general public and of the medical profession, which previously opposed the diagnosis, now reject the findings of the expert commissioners, and he maintains that the primary cause of this lay in the postponement of the publication of the report of the Commission. This period of delay on the part of the Government authorities was seized upon to discredit the findings of the Commission. On this subject of delay we expressed our opinion at the time. We could conceive no adequate reason for it, and we believed then, as our correspondent maintains now, that it was a mistake. But this feature of the case we do not intend to discuss here and now. Our intention has been chiefly to present a statement of the situation which we think is authoritative and will go a great way to distribute just praise to some of the local physicians who have been misrepresented. In this connection we may say that it appears not a little odd that the *Public Health Reports* of the U. S. Marine Hospital Service have published no report of a case of plague in San Francisco since April 4th. Before that time a few cases were being reported right along, and the Plague Commission had had no difficulty in picking up cases. What has become of the Plague in San Francisco? Its sudden disappearance after the departure of the Commission has a dubious aspect.

A Retrograde Movement.—The Post-Office Department of our Government, like the United States Constitution, was made for the people, and not the people for it. It was not intended primarily as a money-making business. It is to serve the convenience of the public; to promote the interests, and, above all, to serve for the enlightenment of the pop-

ulace. But there is great danger that some of these objects will be defeated if Third Assistant Postmaster General Madden is to have his way in ruling out of the privileges of second-class matter all periodicals that offer premiums to their subscribers. Mr. Madden seems to be worried because a certain concern sold tea-sets, claimed to be worth two dollars apiece, as premiums for a publication which was sold for one dollar a year. That certainly looks like anything but a literary or educational enterprise, and may have been an imposition on the Department; but it does not follow that all the legitimate periodicals in the country that do an honest business by offering premiums (which, in most instances, are books) should be debarred from the privileges of going as second-class matter. Some discrimination should certainly be made; some judgment and common sense should be displayed. We enter a protest here in the name of all legitimate journalism, and in the interest of the public which desires and must have its reading matter on reasonable terms. Let there be no tax on letters.

A Venereal Disease of Horses.—The Sixteenth Annual Report of the Bureau of Animal Industry, Washington, D. C., contains an interesting account of the "Maladie du Coût" in horses, as observed in Nebraska. The infection in this case was traced in part to a stallion of the Clydesdale breed, which had been used for breeding purposes. A number of autopsies are reported in animals of both sexes which had been killed after the disease was discovered in them. In the male the affection is a local one, beginning in the penis, but involving sometimes the sheath, scrotum, and testicles. An edematous swelling extended in one case along the abdomen nearly to the forelimbs. An offensive purulent discharge occurs, and the entire end of the penis may slough away. The local sore is an ulcer, covered with a black scale. A skin eruption, consisting of large white maculae, is observed. The animal emaciates and has to be killed. In the mare the infection may invade the whole genital tract and all the reproductive organs. In one case the white spots were seen on the perineum and mammary glands; the vagina was highly congested; the walls of the uterus were thickened, the inner surface being covered with a thick jelly-like exudate; and the ovaries were swollen to several times their normal size. These organs were the seats of extensive changes. There may be some systemic infection as shown in the mesenteric glands and spleen. This report contains no history of any bacteriological investigations, the accounts of the autopsies being confined to a description of the gross pathological conditions. The disease is evidently transmitted by coitus, and beginning as a local sore gradually extends, and may even invade the general system.

Reviews.

The Theory and Practice of Military Hygiene. By Edward L. Munson, A. M., M. D. Illustrated. William Wood & Co. New York. 1901.

The subject of military hygiene is so peculiar, and involves so many features that do not ordinarily occur in works devoted to sanitation, that we confess we have read the book more for the purpose of instruction than in a critical spirit. It is an imposing volume of 983 pages, and appears to represent not only the experience of its writer, but the consensus of opinion of all who have considered the subject, and the array of authorities cited is amazing. The work opens with a long chapter devoted to the selection of the recruit. From it we learn that the great majority of enlisted men in the United States army are native born, and that most of them belong to the laboring class. The commonest causes for rejection are diseases of the eye and imperfect physique. The most desirable men for soldiers are short, stocky fellows, between 21 and 25 years of age. In the British army, in which the requirements are not quite as severe as in our own, defective development caused the rejection of 182 men in 1000, just twice the number in the United States. In the next chapter on the development of the recruit, Munson strongly urges that some system of rational and thorough gymnastics be introduced into the United States army, as it is in the armies of Continental Europe, particularly those of France and Germany. There are a number of interesting illustrations showing the benefit derived from systematic exercise. In addition to gymnasium exercise, he believes that competitive games and sports are of the greatest value, particularly wrestling and football. A long chapter is devoted to marching. One of the interesting features of this is the description of the *pas de flexion*, a step that has been partly introduced into the French army, and which is derived from the couriers of the Orient. It has been found that soldiers accustomed to it can march further and more rapidly, than they can by means of the ordinary marching step. It is curious, if true, that for so many centuries we have been misusing our forces in walking. Chapters are then devoted to the water supply, rations, and the clothing and equipment of the recruit. Munson is unqualified in his condemnation of the blanket-pack now employed in the United States. He believes that in all respects it is disadvantageous, loading the men at the worst point, and bringing—when the canteen and haversack are in position—so much weight across the front of the chest that expansion is disturbed. Although the blanket-roll was so satisfactory during the Civil War, he is not inclined to revert to its use, but suggests, instead, one of the more scientific packs, such as the Merriam or the Novior. Some very ingenious contrivances are described for reducing the weight and bulk of the various articles that must necessarily be carried. One of the most attractive is the Preston mess-kit. A long chapter is devoted to camp sites and camps, and another to posts, barracks, etc. Then follow chapters upon the more familiar subjects of ventilation, heating, the disposal of excreta, and personal cleanliness. The discussion of the diseases of the soldier is rather conventional, and involves the repetition of a good deal that can easily be found in the ordinary text-books on the practice of medicine. The statistical tables and diagrams are exceedingly interesting, however, and ought to be extremely valuable to anyone discussing the problems of infectious disease. The mosquito theory for malaria appears to be adopted, and he strongly urges the sterilization of stagnant pools in the neighborhood of barracks by the use of mineral oil. With regard to the canteen the author has no two opinions. He is heartily and enthusiastically in favor of it, and quotes statistics that are seemingly irrefutable. What satisfaction the various so-called religious organizations of this country can derive from their persistent and unintelligent antagonism to this very sensible measure, we cannot conceive. There is more reason for antagonizing the ordinary social clubs of the larger cities. He is also strongly in favor of the exercise of legal control over other forms of vice. Venereal diseases are far more prevalent in the British army than in any other. Next come the colonial troops of the Dutch, and then the United States. All the other countries are considerably below these three. Chapters indicating the gradual exten-

sion of the United States are those upon hygiene in hot and cold climates, and aboard the troop ship. The book will necessarily have a limited circulation, although we believe that the surgeons of many of our military organizations could derive great benefit from its careful study. It is to a certain extent, a pioneer in its class; it appears to be thorough, and the style is clear and polished. We sincerely congratulate the author. [J. S.]

A Syllabus of New Remedies and Therapeutic Measures, with Chemistry, Physical Appearance and Therapeutic Application. By J. W. Wainwright, M. D. G. P. Engelhard & Co., Chicago, 1901. Pages, 229. Price, \$1.00.

This little book appears to have been prepared conscientiously, and is certainly exceedingly useful. In a work of this kind the greatest danger exists that despite the utmost caution, use will be made of it by the manufacturing chemists to exploit some of their wares. For, as is well known, the profits on the successful preparations are so enormous, that they justify, in the minds of the chemists, almost any method that will bring them before the medical profession in a favorable light. Dr. Wainwright has endeavored to avoid this pitfall as far as possible, by including "only those products whose chemistry is known, or whose exact formulas are given." As a result, some of the most widely advertised, and therefore widely used preparations, do not appear, and we regard this as a most desirable feature of the book.

In addition to drugs a few other remedial measures are mentioned. A considerable section is devoted to anesthesia, another to animal preparations, a third to cold and heat, a fourth to the hemostatic properties of gelatine, and others to hot air, saline infusions, the Nauheim treatment, the Röntgen rays, and serum therapy. In addition, new uses of familiar remedies are included. Thus, he mentions the hypnotic effect of apomorphine; the use of carbolic acid in tetanus, and the value of picric acid in burns. He is rather opposed to the payment of creosote in tuberculosis, and we think, is unreasonably positive in asserting the opinion. A few defects in the book may be noted. Many names are quoted, some of them familiar, and some quite the reverse. In either case the statement of their views is necessarily brief in view of the considerable number of preparations discussed, and therefore it is not always possible to do justice to their opinions, or to include all the details regarding the indication and administrations for each individual preparation, that may be found in the original article; and yet, in the great majority of cases, the journals in which these articles appeared are not mentioned, and when they are, neither date nor volume is given. This we regard as a most serious blemish. A few lines in fine print appended to each article, in which should be given two, three, or more references to important articles on the subject, especially referring to those in which the literature has been given, would not greatly increase the bulk of the book, and would enhance its value very considerably. We hope that this defect will be supplied in the next edition. In reading the various articles we cannot help being impressed by the very favorable tone of most of the criticisms. This is due to a defect inherent in mankind, which consists of an unwillingness to report failures. If the medical profession could be persuaded to write condemnatory reports regarding these new preparations, if they find them useless, the bad ones could be weeded out much more rapidly than they actually are. Our personal experience with the book has been that it is suggestive and helpful. [J. S.]

The Acute Contagious Diseases of Childhood. By Marcus P. Hatfield, A. M., M. D. 142 Pages. Price \$1.00. G. P. Englehard & Co., Chicago.. 1901.

It is very difficult to understand why this book was ever written. There does not appear to have been any necessity for its existence. As the author himself says, it contains no original work, and is very apparently a "composite," if he likes that word. It is very carelessly thrown together, and the author appears to have used only one or two articles in the preparation of the account of each disease, supplemented by some text-book on the practice of medi-

cine. The author seems to be very uncertain how diseases should be treated, and arranged his headings rather differently in different instances.

Of the diseases discussed the greatest amount of space is devoted to scarlatina.

The illustrations of bacteria which accompany this article are about as useless as any illustrations we have ever seen. The time that he allows for the quarantine is, we think, rather short, that is, 5 weeks from the beginning of the attack. He admits, however, that the contagion may remain in the clothing for a much longer period.

In the discussion of measles it is difficult to understand why Koplik's spots are described in connection with the pathology of the disease—they are certainly symptoms.

He is rather more skeptical regarding the etiology of Czaplewski's bacillus in pertussis, than are most writers on the subject. As he bases his skepticism upon the indisputable fact that this micro-organism does not produce disease in the lower animals, we must respect his opinion. As an example of the curious confusion that exists throughout the book we quote the following sentence in relation to the treatment of smallpox. "Threatening septicemia should be promptly combatted by the free use of quinine and alcohol, and the child should on no account be allowed to escape from quarantine until the last traces of smallpox shall have disappeared and the child has had an antiseptic bath." [J. S.]

The Peritoneum. By Byron Robinson, B. S., M. D., Author of Practical Intestinal Surgery, Landmarks in Gynecology, and Life-sized Chart of the Sympathetic Nervous System. Pp., 509, with 247 illustrations. Chicago Medical Book Co., 1899. Second Edition.

This valuable treatise opens with a chapter entirely historical, which names those anatomists and students of Nature who from the earliest times have contributed to the knowledge of the peritoneum or the physiology of the lymphatic system. A brief statement of the work of each investigator is given. An introductory chapter on the histology and physiology of the peritoneum is clearly written, and, like the remainder of the work, abundantly illustrated by drawings, many of them original. The writer is not prepared to accept the view of Kolossow and Paladino that the peritoneum is lined by epithelium, often ciliated, and that the term endothelium should be confined to the vascular tubes. He views the peritoneum as a lymph sac.

The consideration given to perineal structure is especially full and complete. No less than 240 pages are devoted to the subjects of the endothelia of the free surface, to the subperitoneal tissue, and to the blood vessels, nerves and lymphatics of this great membrane.

Under the heading of physiology are given the experimental and other evidence which leads to the conclusion that the chief locality of peritoneal absorption is in the diaphragmatic serosa, and that a stream appears to tend in that direction. The various theories which would account for this absorption are considered. The author believes in the existence of stomata, and gives many drawings which show them. A brief chapter on technique, giving reagents, methods and the like, is followed by a condensed resumé of the physiology, as well as brief conclusions bearing upon the problems of abdominal surgery. Among these are: That irrigation is not theoretically sound practice, that the vast area of nerve destruction accounts for prolonged reflexes and shock, that the enormous absorptive power of the diaphragm makes it an extremely dangerous locality for infections.

An extensive bibliography covers no less than 103 pages, thus completing a work which abounds in evidences of great labor and research, and which cannot fail to occupy the position of classic in this department of investigation.

[G. E. S.]

Manual of the Diseases of Children. By John Madison Taylor, A. M., M. D., and W. Wells, M. D. Second Edition; Thoroughly Revised and Enlarged. Illustrated. P. Blakiston's Son & Co., Phila. 1901. \$4.50.

The authors have undertaken a very thorough revision of the first edition, and have added considerable matter. The book as now published is quite a satisfactory treatise upon

the subject of children's diseases. Whether we needed any more treatises upon this subject is of course a question, but we fear that very little literature is written solely for the purpose of filling a distinct need. The chapter on feeding occupies 61 pages. It is very carefully written, and is, in some respects, thorough. A good deal of it is conventional, but of course that is necessary in a book of this kind. The paragraphs on the contra-indications for breast-feeding, and feeding by a wet-nurse are decidedly too brief. Both subjects could be treated with more detail to the great advantage of the reader. The section on the chemistry of milk, and particularly that part of it treating of the various tests employed in the analysis of milk, is very unsatisfactory. We doubt if anyone would be able to make an analysis that was at all trustworthy, by means of the directions given here. We are not at all sure that this subject could not be better handled in a special work, but if introduced at all it should at least be sufficiently clear and complete to enable a physician to arrive at some sort of a result. On the other hand, the section on the modification of milk, particularly home modification, and that on the diet of children, are really very excellent, and betray considerable practical knowledge of the subject. And this section is after all the practical one for the physician. Of the other sections one of the best is that upon the nervous system. The article on infantile convulsions is particularly good, and the treatment suggested is sufficiently varied to apply to the majority of cases. The others are probably beyond our therapeutic resources. The section on tetany is also very satisfactory. That on epilepsy, on the other hand, appears to us a little too brief, and we think that a little more attention should have been devoted to the general hygienic care of children suffering from this disease. It is hopeless enough at best, but there are probably more chances of at least diminishing its effects in childhood, than at any other period. We do not wish to be considered as finding fault with this book: the points that we have mentioned appear to us worthy of the attention of the authors when they prepare the third edition. On the whole we can cordially recommend the volume to those whose devotion to general practice prevents their making a special study of the diseases of children from the original sources. [J. S.]

"Annual Report of the Smithsonian Institution" for the year ending June 30th, 1899. Government Printing Office, 1901.

This is a very excellent publication, and is one to which we can refer with pride, because it is published by our own Government for the purpose of facilitating the knowledge of scientific progress. The contents consist of 140 pages, devoted to reports, expenditures, etc., and an appendix of more than 500 pages consisting of a "miscellaneous selection of papers (some of them original) embracing a considerable range of scientific investigation and discussion." Among the most interesting of these are the papers on Radio-Active Substances, by H. C. Bolton; the "People of the Philippines," by Rudolf Virchow, "A List of Native Tribes of the Philippines, and of the Languages Spoken by Them," by Blumentritt and an article on "Von Zeppelin's Dirigible Air Ship." The latter is a reprint. But many of the other papers are of even more scientific importance. We note with regret that no bison were born in the Zoological Park during the year 1899. It seems as though this magnificent animal is doomed to extinction. [J. S.]

The Practice of Charity, Individual and Organized. By Edward Thomas Devine, Ph. D., of Pennsylvania. General Secretary of the Charity Organization Society of the City of New York. 1901. New York, Lenthion and Company.

In this little book the practice of charity is discussed by one whose liberal education enables him to treat the subject intelligently from various standpoints. Wide experience, together with careful discernment, is responsible for the clever selection of material: the generalizations are those of the economist, the sociologist, the philanthropist. If the practice of charity needs defence from the attacks of the harsh scientific theorist, read: Charity rea-

sonably bestowed does not perpetuate the unfit but transforms the unfit into that which may profitably survive." This reply to the man who demands for his every action a reason involving expediency. Then to him who is inclined to do duty for duty's sake, but who allows impulse to master reason: "Although it is not the duty of all to be scientifically trained in science or medicine, it is the duty of all to be charitable, and no one is charitable whose attempts at relief result only in the help that harms." How can a given amount of energy on the part of those charitably inclined be directed most advantageously? By an organized corps of professional relief workers, suggests the writer. "In the interest of the Community it is desirable that organized relief work should be recognized as a distinct profession." After discussing "Organized Charity," "Volunteer Charity," "Professional Service," the book concludes with a chapter containing illustrative Problems that require for their wise solution the greatest thought and skill of clergyman, educator, physician. [S. J. L.]

Correspondence.

A FINAL WORD ON SALINE INFUSION IN PNEUMONIA.

BY DR. D. E. KEEFE,
Springfield, Mass.

To the Editor of the *Philadelphia Medical Journal*:—As Dr. Penrose in his reply to my criticism neglected to consider about one half of my arguments, we must assume that they met with his approval or that he considers them unassailable.

I admit that my ideas upon saline infusion were preconceived before the reading of his interesting paper, just as his ideas upon this subject were preconceived before his experiments and before he read my criticism.

I do object to the routine employment of normal saline infusions for I consider it pernicious and unphysiological. I believe that the crest of the wave has been passed, and even in septic abdominal cases it is not relied on nor used as much as formerly.

I assure Dr. Penrose that all my statements are based, not on theory alone, but also on experience and much thought and study.

Regarding the question of edema, there can be no doubt that in pneumonia, as in all other inflammatory conditions, there is both a local edema surrounding the inflamed area, and a stasis of the circulation in the midst of it. The general edema of the lungs is sometimes secondary to heart failure, not always, as Dr. Penrose says in the first part of his sentence, and sometimes secondary to infectious or toxic processes. We agree that primary edema, if such a thing can be said to exist, is of very rare occurrence.

Clinical experience has sufficiently shown that edema of the lungs may complicate pneumonia in the first, second and third stages; that, Dr. Penrose to the contrary notwithstanding, it is an everpresent danger; and that therefore Dr. Penrose's proposal to increase the volume of the circulatory fluid is both unphysiological and indefensible, particularly as he does not increase its carrying power for oxygen. In editorials in the *Philadelphia Medical Journal* and the *New England Medical Monthly*, attention is drawn to the great danger of throwing additional work on the heart and thereby causing pulmonary edema.

It is unfortunate for Dr. Penrose that he has laid so much stress upon Pässler's experiments; because, within a month of their appearance, they were subjected to a vigorous criticism by Hornung in the same *Journal* (April 16th, 1901.) He called particular attention to the inaccuracy of Pässler's statement in regard to the condition of the right ventricle. Pässler's work therefore, appeared to be open to criticism at least. One of the commonest causes of heart failure in pneumonia is degeneration of the myocardium. That it exists is a sufficiently well recognized fact (Osler, Stengel, Birch-Hirschfeld, etc.) and although on some occasions vasomotor relaxation or disturbance of the medullary innova-

tion may contribute to the production of heart failure neither should be considered as of paramount importance. But even if they were, it would be fully as dangerous to add more burden to the heart weakened by disturbed innervation as it would be if the weakness were intrinsic to the heart itself.

There is much doubt as to whether the infusion dilutes the toxins and affects the septic conditions. It is very difficult to understand how it could do it. But the whole question of toxin and antitoxin formation and the development of immunity is at present, in an exceedingly complicated state.

In my first criticism the sentence regarding this subject which he quotes, was printed without the word "germ." It should be: "in the lungs where the germs and toxins are mostly situated, where most of the damage is wrought, they are inaccessible." It is obvious that the toxins must be produced in the lung, and that they must therefore exist in greater quantities in the pulmonary circulation than elsewhere, whether they affect this tissue more seriously than tissues in other parts of the body or not, and that therefore, any attempt at their destruction, would be most effective if it reached them at this point. As however, the circulation in this portion of the lung is sluggish, indeed practically nil, the diluting effect of the infusion could act least at this point.

Regarding Dr. Penrose's claim that the infusions stimulate respiration and increase the oxygen carrying power of the plasma, I can only state that the stimulation of respiration is of very short duration, indeed almost evanescent, and might be claimed as rather a sign of asphyxiation than true stimulation. It is also obvious that the free oxygen that exists in the plasma is merely in transit between the red cells and the tissues that are to absorb it, and does not represent any increased absorptive capacity in the blood.

As to the value of the accentuation of the second pulmonary sound, as an indication for bleeding, I have to say that if we accept bleeding as one of our regular therapeutic measures in pneumonia, then I acknowledge it is of value, but I am not aware that the profession is yet ready to retrace its steps. According to Osler, and my experience accords with his statements, this sound is always accentuated, and therefore the saline infusion should be contraindicated.

In conclusion I wish to express my opinion that the most serious danger in pneumonia is from distension of the right heart and heart failure, and that this occurs not infrequently may be gathered from the statements of Stengel, Roberts, Osler, Powell, Hornung and many others. I did not oppose Dr. Penrose in his efforts to cause elimination of the toxins, but because, first, he could not accomplish his desire by the means proposed; second, because the dangers of overdistending the heart and diluting the hemoglobin are more serious than that he sought to avert; and third, other means to which I drew attention were quite as effective and much less dangerous.

Finally, in spite of the distinguished company before whom Dr. Penrose's paper was first read, and in spite of the leader in the *British Medical Journal*, inquiry leads us to believe that his methods have not received that degree of approval and imitation that would indicate that they appeal to the profession at large as rational or effective.

A Case of Suppurative Gastritis followed by Recovery.—Ruber (*Germ. Beibl.* 1901, No. 4) reports an interesting case of a young girl of 24 years who was seized without apparent cause with chills, headache, vertigo and gastric pains. There was marked tenderness in the region of the left lobe of the liver. The temperature was below 38° C. On the 21st day she vomited 2400 cc. of sanguinous material containing fetid pus. Soon after this the pains disappeared and the appetite returned. Every morning for two weeks she vomited 100 to 200 cc. of similar material. At the 6th week another attack of vomiting began, which again lasted two weeks, and pus was found in the stools. Cure was complete. [T. L. C.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

St. Joseph's Hospital Residents.—The following are the successful applicants for internships at St. Joseph's Hospital: Drs. Foulkrod, Riegel, Homer Rhode, Mervin R. Taylor and Lamott.

Scarlet Fever in Darby.—An epidemic of scarlet fever is existing in Darby. About 40 cases have been reported and many more are under suspicion. Several have died of the disease and it may be necessary to close the schools in advance of the regular vacation period.

The 1876 Class of the Department of Medicine of the University of Pennsylvania held its First Annual Banquet at the University Club, Philadelphia, at seven P. M., on Alumni Day, the 11th of June, and effected a permanent organization for the benefit of its Alma Mater. The following officers were elected: President, Charles A. Oliver, A. M., M. D.; vice-president, William H. Klapp, A. M., M. D., secretary, Francis M. Perkins, A. M., M. D.; treasurer, Benjamin F. Baer, M. D., with an Executive Committee of twelve members who will meet at the call of the President.

Pathological Society of Philadelphia.—At the meeting held June 13, Dr. William E. Robertson showed a specimen of **venous thrombosis in cardiac disease**. The right innominate, axillary, brachial, and external jugular veins contained thrombi. The unusual points in the case were that the cardiac lesion was aortic instead of mitral and that the thrombosis was on the right side instead of the left.

Drs. W. E. Robertson and Ellis E. W. Given reported a case of **sarcoma of the small intestine in a child of 5 years**. Operation showed the impossibility of removal. Autopsy revealed a tumor 15 cm. in diameter, involving the jejunum. The growth was adherent to the rectum, sigmoid, and bladder but no metastasis was present.

Dr. David Riesman detailed a case of **multiple abscess of the liver**. The case was remarkable for the absence of symptoms found at autopsy and also revealed by the exploring needle shortly before death. There had been no dysentery, there was no leukocytosis or jaundice, and the liver was not enlarged or tender.

Dr. R. M. Pearce exhibited four specimens of unusual interest. 1) **Cancer of the esophagus with perforation into the trachea**; (2) **Tuberculosis of the larynx with perforation into the esophagus**; (3) **Cancer of esophagus and tuberculosis of the larynx**; (4) **A dilated esophagus**.

To Inspect Institutions.—A party, consisting of Dr. John V. Shoemaker, President of the Department of Charities and Correction; Dr. James N. Tyson and Dr. Simon Flexner, University of Pennsylvania; Dr. Hobart A. Hare and Dr. Orville Horwitz, Jefferson Medical College; Dr. James Anders and Professor William Ashton, Medico-Chirurgical College; Dr. Ellwood R. Kirby and William J. McLaughlin, members of the Department of Charities and Correction; Peter E. Costello, Chairman of Finance Committee, City Councils; Horn R. Kneass, Chairman of Committee on Department of Charities and Correction, and William M. Geary, Superintendent Bureau of Charities, left for Boston, for the purpose of investigating the manner of conducting locations and other matters connected with the charitable institutions owned and operated by the cities of Boston and New York, also the State institutions in those two cities to learn any facts that may inure to the benefit of the citizens of Philadelphia in the reorganization of the Bureau of Charities, namely the removal of the Philadelphia Almshouse and the Insane Asylum from the grounds located at Thirty-fourth and Pine streets.

Vital Statistics of Philadelphia for the week ending June 15, 1901:

Total Mortality	380	Cases.	Deaths.
Inflammation of the appendix 3,			
bladder 1, brain 11, bronchi 8,			
heart 2, kidneys 21, liver 2, lungs			
18, peritoneum 6, stomach and

NEW YORK.

Epidemic of Measles Among Eskimos.—An epidemic of measles exists among the Eskimos at the Pan-American Exposition. A number of deaths have already occurred from this disease.

Sing Sing Prison Condemned.—The famous State prison at Sing-Sing, New York, has been condemned by the Board of Health of that State as unsanitary, and its removal to a higher situation is recommended. The prison is situated near the edge of the Hudson river, and it was found that at high tide the floor of the prison is only four feet above the water level. As a result of this condition the sewage in the drain-pipes is backed up into the prison, and owing to imperfect discharge, it decomposes.

NEW ENGLAND.

The Massachusetts State Medical Society celebrated its 120th anniversary June 12. Dr. Frank W. Draper, president of the society, presided. Among the prominent men and delegates present were: President Eliot, of Harvard. President Capen, of Tufts; Samuel J. Elder, Dr. W. W. Eaton, Dr. David W. Cheever, Dr. J. M. Storer. Delegates—Maine, C. D. Smith, Portland; C. J. Marston, Bath. New Hampshire, P. W. Parsons, Portsmouth; F. A. Stillings, Concord; A. G. Straw, Manchester. Vermont, A. S. M. Chisholm, Bennington; E. G. Roberts, Fair Haven. Rhode Island, G. L. Collins, Providence; C. V. Chapin, Providence. New York, Parker Syms, New York City; I. S. Haynes, New York City. New Jersey, S. A. Hefler, Hoboken; J. A. Exton, Arlington. Pennsylvania, J. J. Koser, Shippensburg; G. G. Harman, Huntingdon.

Smallpox in Maine.—Another suspected case of smallpox has developed in Bangor in the same house from which four suspects have already been taken to the pest-house. One of the men in quarantine at the Queen City Hotel escaped, and has not yet been recaptured.

Rhode Island Medical Society.—The annual meeting of the Rhode Island Medical Society was held June 6 in Providence, R. I. The annual address was made by Dr. G. Alder Blumer, of Boston. This was followed by the annual banquet. The Massachusetts Society was represented by Dr. T. W. Spencer, of Hingham, and Connecticut by Drs. C. A. Allen and D. W. Richardson. The principal officers elected were: President, George F. Keene; vice-presidents, William R. White and Christopher H. Banker.

WESTERN STATES.

Chicago Pathological Society, May 13th, 1901. Dr. L. Hektoen, president. Dr. I. B. Dismond presented a paper on "The Cellular Changes in Tuberculous Meningitis." Plasma, lymphoid and phagocytic cells form the greater portion of the cell-infiltrations in the vascular and extra-vascular areas of the leptomeninges in acute tuberculous meningitis. The plasma and lymphoid cells migrate largely from the lymph spaces of the arterial adventitia and from the finer capillaries. They proliferate largely by indirect division, a certain number, however, are derived from lymphoid cells. There are two kinds of phagocytes (1) those which proliferate from the endothelial lining of the capillaries and lymph spaces, and (2) those from the subendothelial intimal connective tissue.

The most important of the vascular changes—the tuberculous endarteritis—develops in the following manner: Plasma and lymphoid cells accumulate underneath the endothelium of the intima; later the subendothelial intimal connective tissue cells are found mixed with the former. They proliferate next to the elastic coat, are to a certain degree phagocytic and resemble epithelial cells. They also run together and form giant cells, and in this manner characteristic intimal tubercles develop. Changes of the endothelial lining of the arteries occur later, especially when there is caseation or hyaline degeneration of the collection underneath.

Of interest is the great production of plasma cells which is analogous to the cell changes described by Councilman in acute interstitial nephritis, while on the other hand, the production of phagocytic cells is analogous to the cell changes described by Mallory as occurring in typhoid fever.

Dr. Mewellyn F. Barker presented gross and microscopic specimens of the buboes and internal organs removed from Chinese, dead of plague, in San Francisco. The demonstration was accompanied by a brief description of the pathology and pathogenesis of bubonic plague. In the bubonic form of the disease the lesions in the lymph glands and surrounding tissues—edema, hemorrhage and necrosis—are very characteristic. The changes in the spleen are more marked in the septicemic form than in the bubonic form. The specimen of spleen under the microscope showed extensive necrosis of the splenic framework and pulp, with wandering in of polymorphonuclear leukocytes.

Primary plague pneumonia is distinguished from aspiration pneumonia and from embolic pneumonia occurring as complications of plague. The enormous number of bacilli present, the abundance of blood in the exudate, and the small part played by fibrin are interesting features.

The question of portal of entry was discussed in connection with the various clinical types, and an effort was made to explain the fact that local lesions in the skin and mucous membranes and lymphangitis are rarely present, the first outspoken lesions occurring in the nearest packet of lymph glands.

Dr. Leo Loeb demonstrated microscopic sections showing the difference between the atresia of follicles in different stages of maturity; also microscopic sections of two ovaries of a guinea pig in which all follicles presented the picture of hypertrophy of the epithelium and in which the atresia without exception started by the ingrowth of connective tissue and capillaries into the follicular epithelium. Two slides were demonstrated showing follicles in the process of atresia, each one of which contained two ova. In one of these two follicles both eggs showed progressive changes, in the other follicle one ovum was unchanged and well preserved, the other ovum was segmented. In a third atretic follicle, of which a slide was shown, in which three ova were present; two of these were unchanged, the third ovum had undergone certain changes, the exact nature of which could not with certainty be determined. Another specimen showed a structure resembling very much a small corpus luteum, in the center of which, however, two successive sections demonstrated the presence of an ovum. At present it must be left undecided, if in this case the ovum of a ruptured follicle was retained and a corpus luteum had formed around it, or if under certain conditions a follicle which had not ruptured previously might in the stage of atresia give rise through hypertrophy to a structure similar to a small corpus luteum.

Dr. Maximilian Herzog presented a gastrolith composed of persimmon seeds which had caused perforation of the

stomach and death in a three-year-old boy in the practice of Dr. Cargile, of Bentonville, Ark.

Epidemic of Diphtheria.—There is quite an epidemic of diphtheria at Svensen, Ore. Several children have died of the disease, and a number more are seriously ill with it.

The Mortality Statistics of St. Louis.—The *St. Louis Medical Review*, commenting upon the St. Louis mortality statistics, quotes the following: The greatest mortality in any period after the first decade was over 70, with 1149 deaths; the next greatest was from 35 to 40, with 563 deaths. There were only 8 deaths from puerperal fever, which is a favorable showing for the obstetricians; 25 deaths are ascribed to surgical operations. Heat stroke caused the death of 25. There were 130 suicides.

The Plague Resolutions of the California State Medical Society.—Through the kindness of Dr. Emmett Rixford, who proposed the resolutions which were passed by the Medical Society of the State of California at its last meeting, we are enabled to publish a correct copy, which reads as follows:

"Whereas, It has been shown by our local bacteriologists, and by the Commission sent by the United States Government, that the bubonic plague has existed in San Francisco, and probably does at the present time; therefore, be it

"Resolved, That the Medical Society of the State of California express its confidence that the San Francisco Board of Health, the State Board of Health, and the United States Commission will be able to watch the disease, and to take proper measures for its suppression."

This correction renders the position of the State society much more satisfactory, and justly gives our local bacteriologists due credit for their very efficient and thorough work. In this note Doctor Rixford very appropriately says: "I wish the official report of this affair to contain reference to the fact that our local bacteriologists demonstrated the presence of the plague."—*Occidental Medical Times*

SOUTHERN STATES.

Christian Scientists Cannot Practice in Georgia.—Judge Lumpkin, of the Georgia Superior Court, has denied the application for a charter for "The Atlanta Institute of Christian Science," the effect of his decision being that Christian Scientists cannot practice their treatment of diseases in the State of Georgia without having regularly graduated in medicine and passed an examination before the medical Examining Board, the same as other physicians.

Delaware State Hospital for the Insane.—At the meeting of the trustees of the Delaware State Hospital for the Insane, at Farnhurst, June 7, Dr. John J. Black was re-elected President and Dr. Paris T. Carlisle Secretary.

Dr. R. J. Preston, Superintendent of the Southwestern Hospital for the Insane, of Marion, Vt., has been elected president of the American Psychological Society.

Charlotte Williams Hospital.—Work on the Charlotte Williams Hospital will begin this week. It is to cost \$150,000, and will be one of the largest and best equipped institutions of the kind in the South.

The Trained Nurses' Association of Virginia expect to form an organization in the near future.

MISCELLANY.

Cats and Valerian.—It is a matter of popular knowledge that cats evince curious emotional disturbances when presented with the valerian plant, so great is their fondness for this form of inebriety; for it appears to induce in them a species of intoxication, that the plants in the garden undergo premature decay if there are any cats about. Nor is this influence confined to cats, for rat-catchers, it is stated, employ the roots to attract rats for purposes of slaughter. In a novel which was recently reviewed by our contemporary, *The Saturday Review*, we note a curious episode which turns on the incident of a cat having been attracted to a corner of a room where some tincture of valerian had been spilled. Unfortunately for the probability of the author's ingenious fancy, the tubercular preparation of valerians do not possess

the property of attracting cats, and the animal, if offered a sniff of the tincture in a glass, turns from it with silent contempt, when, indeed, its attitude is not suggestive of disgust. The author may be pardoned his ignorance of this peculiarity, which is doubtless shared by many persons who pride themselves on their knowledge of materia medica, but the curious inertness of pharmaceutical preparations of the plant in this direction inspire a diffidence as to their therapeutical efficacy when administered to human beings. The action of valerian in man is not one which admits of ready estimation, and we would commend this doubt to the attention of the editors of the British Pharmacopoeia who may think it worth while inserting a proviso among the tests to the effect that no preparation of valerian which fails to excite the cat is to be regarded as orthodox.—*Med. Press and Circular*.

Obituary.—Dr. L. S. Tesson, at Vancouver, Wash., on June 7, aged 59 years.—Dr. C. B. Brooke, at Baltimore, Md., on June 11.—Dr. Charles Scott Seebold, at Baltimore, Md., on June 12, aged 51 years.—Dr. Arthur J. Dresser, at Tewksbury, Mass., on June 12, aged 28 years.—Dr. Frederick L. Nutt, at Marengo, Ill., on May 23, aged 49 years.—Dr. Conrad Wienges, at Jersey City, on May 23, aged 53 years.

Plague in Turkey.—In Bagdad, on May 6th, a 30-year-old Kurdish woman, the wife of a dealer in old clothes, died of a disease which showed all the symptoms of plague. All persons who had been in contact with the woman were placed under strict medical observation. By the orders of the supreme sanitary council in Constantinople, 2 temporary hospitals have been erected in Bagdad for the accommodation of those accompanying the passing caravans, and in which the travelers have to submit to five days' quarantine. The effects of the travelers are there subjected to a chemical disinfection and then daily exposed to the rays of the sun. Ships which have to leave Bagdad for the South have to undergo five days' quarantine in Gavarah. Cavalry patrols are to keep watch over the country between Bagdad and the hospitals, in order to turn back any fugitives. Official doctors and military physicians are to be sent into the neighboring villages of Bagdad in order to supervise the sanitary condition of the population. The duty of reporting every fresh case of plague will be strictly enforced.

Plague in Egypt.—On May 5 the corpse of a 6-year-old girl, who had apparently died of the plague, was brought to the Government hospital at Alexandria from the part of the city known as Tombgieh. The bacteriological examination confirmed the suspicion that the plague was the cause of death, and the necessary precautions were taken accordingly.

Outgoing vessels have been ordered to enter on the ship's papers corresponding remarks, and must undergo medical inspection and disinfection.

Plague in British East India.—During the week ended April 19, there occurred in the Presidency of Bombay 1646 fresh cases and 1360 deaths of plague—that is to say, 301 cases and 272 deaths less than during the foregoing week. In Karachi, however, a decline of the disease is not to be noted. From this port during the last week there were 236 fresh cases and 210 deaths reported. In the city of Bombay, during the week ended April 20, there were reported 704 fresh cases (67 less than during the previous week), and 563 deaths proved to be due to plague. In addition, of the total, 1514 deaths in the city, 428 were designated as suspected plague.

Changes in the Medical Corps of the Navy, week ended June 15th.

ASSISTANT SURGEON C. M. MAYERS, appointed assistant surgeon from June 1—June 7.
ASSISTANT SURGEON J. F. MURPHY, ordered to Naval Academy, June 17—June 8.
SURGEON A. R. WENTWORTH, detached from the Albany and ordered to the Albatross, June 1.
SURGEON H. N. T. HARRIS, detached from the Albany and ordered to the Monocacy, June 1.
P. A. SURGEON S. G. EVANS, detached from the Monocacy and ordered to the Scorpion, June 1.
ASSISTANT SURGEON J. W. BACKUS, ordered to the Vermont, June 1.
ASSISTANT SURGEON F. A. ASSERSON, ordered to the Naval Hospital, New York, June 17—June 11.
ASSISTANT SURGEON G. M. MAYERS, ordered to the Pennsylvania, Navy Yard, June 15—June 17.

Official list of the changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 14 days ended June 13, 1901.

J. H. WHITE, surgeon, detached from Washington, D. C., for Philadelphia, June 7, 1901.
L. W. WILLIAMS, surgeon, granted leave of absence for 3 days from June 12—June 14, 1901.
Granted 2 days extension of leave of absence—June 8, 1901.
W. J. PETTUS, surgeon, granted leave of absence for 3 days from June 12—June 14, 1901.
J. A. NYDEGGER, passed assistant surgeon, granted leave of absence for 30 days from June 8, 1901—June 8, 1901.
H. A. STRAIN, passed assistant surgeon, granted leave of absence for 30 days from May 18—May 18, 1901.
H. W. WICKES, passed assistant surgeon, granted leave of absence for 4 days from June 7—June 11, 1901.
C. E. DECKER, assistant surgeon, granted leave of absence for 10 days from June 4—June 14, 1901.
W. W. KING, assistant surgeon, granted leave of absence for 4 days—June 11, 1901.
J. E. BREADY, acting assistant surgeon, granted leave of absence for 1 day, June 19—June 11, 1901.
HENRY ECROYD, acting assistant surgeon, granted leave of absence for 10 days from June 5—June 6, 1901.
W. C. MASON, acting assistant surgeon, granted leave of absence for 6 days from June 23—June 10, 1901.
F. R. SMYTH, acting assistant surgeon, leave of absence for 3 days granted Acting Assistant Surgeon Smyth by Bureau telegram of May 31, 1901, received June 1, 1901.
J. G. STANTON, acting assistant surgeon, granted leave of absence for 15 days from June 1—June 16, 1901.

BOARD CONVENED.

Board convened to meet at Washington, D. C., on June 7, 1901, for the physical examination of an applicant for cadetship in the U. S. Revenue Cutter Service. Detail for the Board—Passed Assistant Surgeon H. D. Geddings, Chairman; Assistant Surgeon B. S. Warren, Recorder.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended June 15, 1901.

GREAT BRITAIN, ETC.

Plague in Hong Kong.—The colonial office has received a dispatch from Sir Henry Blake, Governor of Hong Kong, announcing that 215 cases of bubonic plague were reported for the week ended June 1, and that the total number of deaths thus far from the disease is 207.

CONTINENTAL EUROPE.

A Festschrift to Professor Bottini.—A Festschrift on surgery will be presented to Professor Bottini with a gold medal and a framed parchment list of all subscribers in honor of the twenty-fifth anniversary of his appointment to the chair of surgery at Pavia.

A New Method of Counting the White Corpuscles has been devised by Kourloff (*Vratch*). It is a dry method, and consists in drawing the blood into a graduated pipette, depositing a thin film on two cover-glasses, whose surface is measured by a network of lines. The white cells are then counted and the area measured by means of the movable stage and Ehrlich's diaphragm. This method allows the operator to work without haste and the results can be verified at any time. The writer asserts that he can count from 1000 to 2000 more white cells than by the Thoma-Zeiss cell, the dilutant in that method changing and destroying some white cells.—*American Monthly Microscopical Journal*.

A Novel Diversion for the Insane.—In one of the city hospitals for the insane in St. Petersburg a stage was erected on which light vaudevilles are produced. The actors, as well as the audience, are the patients themselves, the former proving in every respect equal to the task, while the latter seem to derive real enjoyment from the affair.

Drunkenness in St. Petersburg.—Within the last year 8330 persons were arrested on the streets for drunkenness.

Convicted for Rape.—A former professor of the Warsaw University was sentenced to 2½ years in the workhouse followed by 4 years of police supervision and deprivation of all rights and privileges for having committed rape.

The Detection of Human Blood.—A method for detecting human blood has been suggested by M. S. Cotton in the *Bull. Soc. Chimique de Paris*. It depends upon the fact that blood will liberate oxygen from hydrogen peroxide. Using 1 c.c. of blood with 250 c.c. of hy. per., he obtained for man, 580 to 610 c.c.; for horse and pig, from 320 to 350 cc.; for ox, 165 to 170; for guinea pig, 115 to 125, and for sheep, from 60 to 65 c.c. This large excess in man over all the lower species would seem to be of diagnostic value.

Pyloric Obstruction.—In demonstrating a specimen of a pylorus excised for obstruction, Dr. E. Lambotte (*Presse Medicale Belge*, 1901, No. 18) called attention to the efficacy of sodium bicarbonate in gastric affections, and to the extreme frequency with which they are of pyloric origin. He believes that comparatively few cases of stomach trouble are of nervous origin. The specimen shown was a hypertrophic pylorus, removed by Dr. M. Bernard from a woman of 37, in whom symptoms of gastric disturbance had existed for three years. Gastro-duodenorrhaphy with pylorotomy was performed, and she went home two weeks later, cured.

Society Reports.

FIFTY-SECOND MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

[Conclusion.]

SECTION ON MATERIA MEDICA, PHARMACY AND THERAPEUTICS.

N. S. Davis, Jr., Chicago, Chairman; Frank Woodbury, Philadelphia, Secretary.

MEETINGS HELD IN SENATE CHAMBER, STATE CAPITOL, ST. PAUL.

(Communications.)

FIRST DAY, JUNE 4th.

"Experimental Work in Intra-organic and Venous Injections and Blood Extracts in the Cure of Acute, Organic Diseases," by W. Byron Coakley, of Chicago. The principal object of this paper was to show the great therapeutic value of sodium chloride, and especially of subcutaneous and parenchymatous injections of normal salt solution, with instruments specially devised for the purpose. He claimed that the injections were innocuous, and that he had not produced hematoma even in solid organs, such as the liver, the kidney, or spleen. An instrument used for the purpose of making the injections at the proper temperature and at a slow rate of speed was exhibited and its construction explained. It consisted of an apparatus on the principle of an aspirator, having a double chamber, the external one being filled with water at a temperature of 120° F. during the time of injection. The flow of the solution was regulated by the slow revolution of a milled wheel by hand, on the principle of the microtome. He also presented two cannulas, each having a lateral opening, the inner one having a closed extremity. These were introduced into the selected vein, of a dog, for instance, in opposite directions and at different places, so that their points could meet and pass each other, the closed point slipping into the open one. Being fastened in this position, it was only necessary to give the inner tube a quarter revolution in order to permit the blood to flow through the tube, or a normal salt (seven-tenths per cent.) solution, injected, as might be desired. Results in the form of increased action of the heart and strength of the pulse, relief from shock and increase of vitality were reported. It appeared to have a special antidotal effect to carbon dioxide and in preventing and overcoming asphyxia. It takes the place of transfusion of blood, especially after loss of blood by hemorrhage. The lecturer reported an experiment in which repeated bleedings were made until a dog's heart action was so weak as to be almost extinguished. After the injection of salt solution directly into the pericardium, the heart beat with greatly increased force; and, after intravenous injection of salt solution, the animal in a few hours was restored to a normal condition. In this discussion the lecturer stated that he had only resorted to parenchymatous injection in the human lung in one case of acute lobar pneumonia. It was done during the stage of hepatization. He had used a very fine needle with which to inject the salt solution into the interior of the consolidated lung. The next day, mucous rales could be heard over this area, and the patient went on to speedy recovery. He believed that the injection shortened the course of the disease, and that this treatment deserved further trial.

Neglected, but Valuable, Therapeutic Measures, was the title of a paper read by Geo. F. Butler, of Alma, Michigan. After reviewing a number of methods and remedies, which were popular before the scientific era in medicine, many of which were deservedly abandoned, *e. g.*, skatological remedies, animal products, etc., he directed attention to some measures which should not be neglected by the profession. Prominent among these is blood-letting in a class of cases in which its powerful physiological properties would be desired. Among these he cited cases of toxemia, in which the depleted blood could be substituted by normal salt solution. Counter irritation is a neglected, but a valuable therapeutic resource, in illustration of which he directed

attention to the remarkable change for the better in the condition of some cases of insanity after accidental fracture of a bone. Bathing, used in typhoid fever with great advantage, is also very valuable in yellow fever. The combination of drugs in a single prescription has fallen into undeserved disrepute as polypharmacy, but he claimed that very often a combination of remedies so modified their action that a new and superior therapeutic agent was obtained, for instance, the combination of iron with the simple bitters in the treatment of chlorosis, especially for overcoming anemia in children. The infusion of quassia combined with aromatic sulphuric acid and tincture of iron, he is accustomed to give with great advantage for this condition. The sexual erethism seen in the condition of auto-toxism, is relieved by (1) removal of toxic agents by purgatives and (2) by heart toxics. A valuable but neglected agent for the latter purpose is copper sulphate and copper arseniate, given in small doses. Massage is also a measure not sufficiently appreciated. He especially recommended a combination of massage, hydropathy and out-door exercises as having great restorative value. Suggestive therapeutics is worthy of more study as a potent agent for good and of great value when used in conjunction with other measures just referred to.

The Therapeutic Indications Presented by the Blood in Disease," was the subject of the next paper, by Dr. O. T. Osborne, of New Haven, Conn. A word of caution was expressed against the ultra-scientific attitude on the part of physicians, who often overlook the individual element or personal factor in the case. We should never forget the man who has the disease and his individual condition and needs. Departures from health do not always conform to clinical types, thus, it is not necessary to have all the characters of Grave's disease present in early thyroid disease; in every case of deficient thyroid secretion, some disturbance of health will doubtless be produced of marked character. For instance, he believes that many cases of neurasthenia have their true explanation in this deficient function of the thyroid and such cases are greatly benefited by the administration of the thyroid extract. In a similar way, other patients may have a disturbance of the adrenal function, without typical symptoms of Addison's disease, but with other clinical manifestations, which improve under the same kind of treatment. In obscure conditions of disease good results generally follow attempts to correct or aid the normal metabolism of the body. Very important in this connection is the condition of the blood. The increase of diminution of red corpuscles and of hemoglobin, of the leukocytes, or lymphocytes, may be accompanied by evidences of disturbance of function. Alterations of the density of the blood-plasma in its relations to osmosis are significant, also of the total quantity and the distribution of blood in the body. Vaso-motor ataxia plays a very important part in many functional disorders, notably in neurotics and neurasthenics, and also in hysteria. In great sudden diminution of red blood cells from hemorrhage, or in malignant infections, the patients die, suddenly, with symptoms of acute anemia, a condition which the author termed "medical shock." To prevent this, he advised the administration of iron in acute infections, especially in typhoid fever, the tincture of the chloride being especially applicable, as it is in erysipelas, and in diphtheria.

"On Chronic Myocarditis," by Dr. John H. Musser, of Philadelphia. In this communication, the lecturer differentiated between the forms of chronic myocarditis, so commonly occurring in infectious diseases, and the primary form to which he especially directed his remarks. The condition is accompanied by sclerosis or endarteritis of the coronary arteries and might be called coronary artery disease. In these cases, especial attention must be paid to the hygienic management. The medicinal treatment depends very much upon the general conditions present and also upon associated lesions which have taken place in the heart and other organs. The habits of life should be carefully studied and regulated according to the case, and business either abandoned entirely or its responsibilities and activity much reduced, according to the ability of the heart to perform its work. Careful study of the digestive capacity and the character of the food must be made. Often there is inability to digest sufficient food. The recuperative power of the individual, as indicated by his abil-

ity to continue his work, without feeling fatigue, and his response to bathing also must be considered. Hot baths, vapor or steam baths are useful where the gouty or rheumatic diathesis is present, but ordinarily, a warm sponge bath at night with moderate friction will be all that is necessary in the line of hydrotherapy, though should the patient be accustomed to the shock of a morning cold bath and it agrees with him, it may be continued. As the rule, no changes are made in the habits of life of the patient unless they are considered to be injurious. The medical treatment depends upon the amount of endarteritis and the condition of the heart walls present in the case, and whether high or low arterial tension exists. If low, then digitalis, sparteine, strychnine and other cardiac stimulants are called for; if high, arterial tension is present, remedies are given which decrease blood pressure, such as nitroglycerin, the strontium salts, and similar agents of this class. Purgatives also reduce blood pressure, and salines are advised: magnesium sulphate is very useful, taken each morning in a glassful of water. The treatment of angina pectoris during the paroxysm is so well known that he would not speak of it, but he approved of the prophylactic treatment between the paroxysms by nitroglycerin and iodide of potassium especially, and the avoidance of digitalis and all its preparations which increase blood pressure. The nitroglycerin should be given in increasing doses, until the physiological effects are produced. He had patients who had gradually increased the dose until they took half a drachm of the centesimal solution, two or three times a day, with the greatest benefit. The great object of the treatment should be to reduce or prevent cardiac hypertrophy. These patients must be placed upon a lowered scale of life, because they cannot live on the ordinary scale of other human beings, with ordinary blood tension without having attacks of angina pectoris. The dyspnea of myocarditis is of two kinds (1) that due to dilatation of the heart, (2) that caused by asystole. The former is almost continuous but is increased by exertion. In the latter case the attack is sudden in its onset and is accompanied by frothy expectoration, pain, and the usual symptoms of edema of the lungs, with arrhythmia and asystole. In such cases small doses of morphin hypodermically, with strychnia, and, if there is high arterial tension, nitroglycerin will give relief. If there is venous stasis with lowered tension, the use of stimulants, with digitalis, is recommended. Attention must be directed not merely to the cardiac condition, but also to the cardio-vascular condition, and, in fact, to that of all the organs in the body, in the management of chronic myocarditis.

Discussion.—Dr. Henry Beates, of Philadelphia, agreed with the lecturer on all but one point. He contended that the condition of increased arterial tension never exists in cases of chronic myocarditis and therefore that nitroglycerin and all cardiac depressants were injurious. The agent that had produced the best results in his own experience with a large number of these cases, was a preparation of digitalis, known as digitalin-Germanic (Merck) which did not cause gastric disturbance as did all other preparations of digitalis. He had found the administration of this remedy sufficient to control the condition and cause great improvement in the general condition, with assistance of hygienic management laid down by the lecturer.

Dr. S. E. Solly referred to the effects of high altitudes upon this disease. As the rule such cases should not be sent to high altitudes, but a large number of them do visit Colorado Springs, and he had been surprised to find how well they kept as long as they were careful to avoid unnecessary exertion and live a quiet life. He believed that, all things considered, the best climate for them would be one of moderate altitude, where the air is less dry than at a high elevation, or is moderately moist.

Dr. Osborne said that the new remedy mentioned by the first speakers had not been sufficiently studied to determine its physiological action; for instance, it was not yet settled whether it is a vaso-motor dilator or constrictor.

Dr. Beates said that it was a constrictor. Dr. Osborne said that some of these cases call for a vaso-constrictor and others a dilator, but almost always morphine. He mentioned adrenaline as a useful vaso-motor constrictor. Nitro-glycerin is of great value in cases needing a dilator. He suggested that cases after 45 years of age, might show vascular phenomena, as a result of atrophy or diminished secretion of the thyroid gland.

Dr. Musser, in reply to a question, stated that he gave

iodide of potassium in a glass of milk or in a preparation of pepsin. Some patients can take only one dose a day. He had never been able to get satisfactory results from hydriodic acid and much preferred the potassium salt.

"The Treatment of Obesity," by Heinrich Sterin, of New York, directed attention to the different forms and complications of this condition. He divided polysarcia into three types on the basis of the specific gravity of the individual. (1) Hyperplasmic obesity, or lipomatous hyperplasma, those with relatively high degree of corporeal specific gravity; (2) Metabolic, or common, obesity; those with normal or slightly diminished specific gravity; and (3) hydroplasmic obesity or lipomatous hydroplasma, those with lessened density of the body. The first form is accompanied by high arterial tension and often is associated with latent, or actual, arterio sclerosis. The second form is encountered the most frequently, and is a symptom of bodily degeneration. Obesity of itself is not a disease, but is a link in a chain of symptoms pathognomonic of certain nutritional disorders, and is due frequently to excess of nourishment with diminished exercise. The objection to the dietaries usually given is that, by their rule the patient is underfed. Muscular exercise is essential to the treatment, including massage and all forms of outdoor sports. All measures favoring oxidation, such as calisthenics, hydrotherapy, and balneotherapy are useful. Anti-fat remedies, as a class, are to be condemned, because they are useless in small doses and poisonous in large ones, causing in addition to deprivation of fat, a melting down of body albumin. Some mineral waters, thyroid extract, and fucus vesiculosus are exceptions, and are valuable adjuvants. With thyroid extract (gr.ii) he combines arsenious acid (gr.1-60) and adonidin (gr.1-12), and thus avoids the distressing symptoms produced by thyroid alone. Special diet lists were given from which each case could have its own selection, but laying special stress upon the necessity for exercise and attention to the secretions and the circulation. In the third form, hydroplasmic obesity, reduction of the amount of liquids in the food is advised, and also remedies directed towards increasing the tonicity of the heart. In this condition, thyroid is generally contra-indicated, but the patient will be benefitted by strychnine and iron. During the treatment, examinations into the blood density should be made at regular intervals to determine the results from remedies and the progress of the case.

"The Treatment of Neurasthenia," by H. N. Moger, of Chicago. The author insisted first upon the necessity of correct diagnosis. Hysteria, hypochondria, and other conditions resembling neurasthenia, may be separated from it by attention to history. The characteristic phenomenon of the latter is the "fatigue symptom," or an excessive amount of fatigue following ordinary exertion. Attention was directed towards the importance of distinguishing primary or so-called essential, neurasthenia from the secondary nervous weakness, which results from organic disease or defective nutrition. The latter form is common in all the acute febrile diseases and whenever nutrition is impaired. The diagnosis of the primary form must always be made by exclusion. In the therapeutic management especial value is derived from rest, diet, cold bathing and strychnine, which is the sheet anchor in the drug treatment. Exposure of the patient to the fresh air for several hours a day, even in the middle of winter, was followed by remarkable benefit and increased appetite and powers of assimilation.

In reply to questions from Drs. Shelly, of Kansas; Solly, of Colorado Springs; Stern, of New York, and Putney, of West Virginia, the lecturer explained that all cases of neurasthenia are not pure cases and that hysteria may be complicated with neurasthenia, so that the diagnosis of neurasthenia does not always exclude hysteria. It is important to recognize the neurasthenia, which is due to obesity or kidney disease, as a secondary affection, and not mistake it for the primary form. He had no special diet for these cases except that he insisted upon the patients taking large quantities of milk and cream. The patient is instructed to keep a detailed report in writing each day of his food and his symptoms, which is filed away for future comparison, if the patient should become discouraged and think he is not making any progress. He is encouraged to talk freely with his physician about his symptoms, but is prohibited from discussing them with visitors or the members of his family.

SECOND DAY, JUNE 5.

"Report on Medicines used by One Hundred St. Louis Physicians," by H. M. Wheepley, of St. Louis, Mo., was read by title by the Secretary. "A Plea for More Uniformity and Strength in our Armamentarium," by C. F. Wahrer, of Fort Madison, was an interesting and earnest plea for loyalty to the Pharmacopoeia and scientific prescription writing. He condemned in caustic language the practice of using ready-made proprietary compounds, the composition of which is only partly revealed. "The Standardization of Crude Drugs and Galenical Preparations," was the subject of a communication by A. B. Lyons, of Detroit, a member of the Committee on Revision. He pointed out the fact that vegetable drugs vary greatly in medicinal activity. Scientific medication therefore requires that their preparations be brought to some uniform standard of strength. The present assay methods are confessedly imperfect and unsatisfactory, with few exceptions. An imperfect method, however, which is approximately correct, is better than none. The Pharmacopoeia of 1890 furnished standards and assay processes for opium, cinchona bark, and nux vomica and their preparations. In the revision of 1900 this list will be greatly extended and the assay processes rendered more precise. Standardization by physiological lists has not been adopted by the Committee, but in his opinion, might with advantage be approved to a limited extent. To the physician, the question is of vital importance. He should know what the standards to be established require, and should insist that they give him preparations identical therapeutically, with those he had been accustomed to, when the latter were skilfully made from an average sample of good drug. Among the important questions now before the Committee are the admission of the newer derivations of opium. In the case of nux vomica, an improvement will be made by the introduction of a method of determining the proportion of strychnine, instead of the total alkaloids which vary in their quantity and in their proportion to each other.

C. S. N. Hallberg said that the principle of standardization could be applied to only a limited extent at present and was not applicable to many drugs, like aconite and ergot, in the present state of our knowledge concerning their active principles. F. J. Wulling said that if the Pharmacopoeia prescribed tests for use by the pharmacist that the better class of druggists would undoubtedly apply them and that the others would do so if they found that physicians were interested in the subject and required them. He considered the subject of paramount importance to therapeutists as well as to scientific pharmacy. Dr. E. M. Wilson deplored the lack of knowledge of pharmacy and of the Pharmacopoeia by physicians generally and their apparent indifference to the quality of the drugs and preparations with which their prescriptions are filled. The same prescription might be filled at six different drug stores and each preparation would be different from the other. Dr. Dickerson, of St. Louis, said that the study of materia medica and pharmacy in our medical schools is too much neglected in favor of clinical and laboratory work. He suggested that, instead of being dropped at the end of the first year, these studies should be made obligatory during the whole four years of the medical course.

The Chairman pointed out the fact that the Pharmacopoeia appears to be especially constructed to be a work of reference for the druggist and is not made as useful to the physician as it might be. In his opinion all the new remedies should be introduced into the Pharmacopoeia, whether they have been fully tested or not, so that the physician might find in it all the most recent information about drugs. It should not be a volume of standards, but of reference. Possibly the newest drugs might be placed in an appendix. The older preparations should be retained, although only employed by a few physicians. As regards teaching materia medica, he felt assured that both pharmacy and pharmacology are given a proper amount of attention in our leading medical schools. Students are made acquainted with crude drugs and are taught to make the preparations; this is further supplemented by laboratory studies into the physiological action of drugs. The recent graduates are much better informed upon these topics than those of earlier years.

The Chairman introduced the Delegates from the American Pharmaceutical Association, of whom Mr. C. J. Wal-

ling, of Detroit, was the Chairman. Dr. A. B. Lyons, of Detroit, and C. N. D. Hallberg were among the delegates in attendance. Upon motion, they were invited to take part in the proceedings as members of the Section.

SECOND DAY, AFTERNOON SESSION.

Dr. S. E. Solly addressed the Section on the subject of the **Question of the Theapeutic Value of Residence in High Altitudes for Pulmonary Tuberculosis and the Indications for this Treatment.** The attention given recently to the subject of home treatment does not detract from the value of altitude treatment. There are many persons who cannot leave their homes and the present methods of home and sanitarium treatment are much better than any which have gone before them. Nothing that could be said in favor of altitude treatment should be construed as opposing the home management of many cases of pulmonary disease. Altitude possesses certain physiological properties owing to its peculiar conditions. Among these are diminished barometric pressure. A physiological effect of this is increase of the number of red blood cells and likewise of hemoglobin, thus overcoming anemia and improving nutrition. The immediate effect of altitude is to increase the rate of the pulse and the blood-tension, but in normal individuals the pulse soon returns to the normal and the change of arterial tension is only temporary. There is increased rapidity of the respiratory wave, especially after exertion. Both pulse and respiration are influenced to a greater degree by active exertion at altitudes than at sea-level. The lungs become more active and inspiration is fuller, increasing the chest capacity of the individual who resides in altitudes, such as in the city of Mexico. (Henriot and Lopez). We do not know whether the improvement is due to diminution of oxygen supply or to increase of respiratory effort, probably the latter, at least in great part. Then the dryness of the air at high levels, produces more rapid evaporation from the lungs and the skin, and reduces expectoration. The influences of the increased amount of sunlight has been studied a great deal, and it is very marked in benefitting certain diseases, in others it is too stimulating. The marked alterations of temperature between night and day time, the lecturer believed to exert a strengthening effect upon the nervous system, the cold nights acting something like the cold bath in typhoid fever. The aseptic condition of the air and its freedom from dust are great advantages in the treatment of tuberculosis.

Altitudes vary in temperature according to remoteness from the equator and to local conditions. They may be divided into the cold, the medium and the hot climate. In the health resorts of Canada and the North of Europe, the winters are severe and long. In the hot climates of Arizona and New Mexico, the winters are mild, but the summers are too hot for residence for most patients, and yet there are some consumptives who live there all the year round with benefit. In the hot climate there is more dust than in the cold climates, because in the latter the surrounding ground is covered with snow. Colorado offers a climate between the two extremes. It has more variability of temperature than the others, and is on this account less well suited to elderly patients and feeble persons who cannot exercise. In deciding whether or not a tuberculous patient should be sent to an altitude, something must be considered besides his physical signs. Cases may be clinically divided into purely tubercular, catarrhal, and pneumonic, which is convenient but not beyond criticism. Many cases present symptoms of all three conditions. But this division had proved very useful to the speaker in classifying these patients, in his practice. The purely tubercular cases, usually have a weak heart and are anemic. They need stimulants and the climate of Colorado usually agrees with them, especially if they are properly cared for at first. The catarrhal cases usually have some disturbance of metabolism, or uric acid excretion, which renders them liable to mucous membrane inflammations. When these patients come to Colorado, they have to be carefully guarded, on account of the variability of the climate. Often, they will do better by remaining at a lower level for a time preparatory to going to Colorado. In the pneumonic cases, there is marked tendency towards inflammatory action of sthenic character. They are advised to remain at home under treatment until the disease is less acute and ceases to progress. The climate of altitudes is too stimulating for such cases until the inflammatory action has subsided. Hemoptysis is not a

bar to removal to Colorado, but if the patient has had a recent hemorrhage he should remain at a lower level until the lung tissues have recovered from it and the condition is stationary. Patients do not have more frequent hemorrhages at altitudes than at other places, with proper care. The mental state of the patient is to be considered. If he suffers from home-sickness, he had better not go among strange scenes, where his mental state will make him unhappy. The social state of the individual must also influence the judgment. The rich who can supply themselves with every comfort, will do better than those of moderate means. The out-door laborer also will do very well, and indeed better than those who are accustomed to work in-doors. Most patients of the latter class are better suited for home treatment, although some of them do very well in Colorado. As regards the stage of the disease, if the conditions are otherwise favorable, and in case of cavity, if it be protected by thick walls, the patient will do well at any stage. But, if in cavity cases, the disease is progressing, the patient should be treated in a hospital, in the open air, if possible, until he is in a better condition, to go to an altitude. He urged that the patients themselves should be studied as well as their symptoms, and approved of State sanatoria, where a proper field for observing the cases is provided, and the cases selected which are most likely to improve after removal to an altitude.

The next paper, **"The Adaptability of Southern California and similar Climates to the Needs of Consumptives,"** was read by Dr. Norman Bridge, of Los Angeles, who later also read another communication entitled, **"The Proper Management of the Tuberculous Lung."** In the former, he extolled the advantages of that portion of Southern California, behind the foot-hills, about 25 or 30 miles from the sea, in the vicinity especially back of Pasadena, at altitudes of from 3500 to 6000 feet. Strawberry Valley, in the San Jacinto mountains, at an elevation of 5000 feet, has been selected as an ideal place for a sanitarium for the treatment of pulmonary disease. The slight fluctuations of the barometer, the comparative dryness of the air, the large amount of sunshine and mildness of the climate the year round, he thought, gave the climate of southern California special advantages for this class of cases. In the second paper, he approved of rest for the affected lung and spoke favorably of intra-pleural injections of nitrogen gas. Where this cannot be performed, he advised fixation with bands of adhesive plaster, nearly encircling the thorax, so as to limit the movement of the ribs.

"Nineteen Years' Experience with Creosote in Tuberculosis" was the title of a paper read by Dr. A. Burroughs, Asheville, N. C. The author gave no statistics, but asserted his conviction from personal observation that creosote in larger doses has a curative action in pulmonary tuberculosis. The ordinary dose of five or ten minims is too small, except to benefit a feeble digestion. It is only in large doses (60 to 100 minims) three times a day, by the mouth (given in cod liver oil, whiskey or cream), supplemented by the inhalation of fifteen to twenty minims daily (in some hydro-carbon oil), that the curative effect upon the lungs is obtained. He commences with a dose of twenty, and rapidly runs it up to eighty, minims of beech-wood creosote, given after a full meal, three times a day. He had not observed any cases of renal disturbance or other bad effects from these large doses, but had seen some remarkable cases of recovery.

A paper on **"Specific Therapeutics in Pulmonary Tuberculosis"** was read by Arnold C. Klebs, of Chicago. The author briefly considered the various methods of treatment now in vogue, and concluded that none deserved the title of specific, but in conjunction with sanitarium methods they were of unquestioned benefit, especially the serum treatment. Attempts at immunization have not left the experimental stage, and, without denying the possibility of final success, he would decry the enthusiastic support they have received from certain observers, as being premature and to a certain extent dangerous. In the therapeutic management, the importance of open air, hygiene, and diet, is universally acknowledged, but the reliance upon some supposed specific drug leads the medical attendant to fail in paying proper attention to these measures. A visit to a sanitarium in which all the details of the daily life are systematically and scientifically regulated would convince any one of the superior importance of such

measures over the ordinary methods of drug treatment of pulmonary tuberculosis.

Discussion.—**DeLancey Rochester, of Buffalo,** thoroughly endorsed the remarks commending climatic treatment. He also approved of the use of creosote in large doses in the treatment of tuberculosis and mentioned five cases which had been cured under his observation. The advice to keep the affected lung at rest he also approved. Harm has been done by pulmonary gymnastics, during the time when the disease is active; later when the lung has cicatrized gymnastics may be used with benefit.

Dr. S. C. Benney, of Denver, said that it had been his observation that, as regards hemorrhage at altitudes, one case out of every four which has had bleeding from the lungs before arrival may expect to have a recurrence. If a patient, however, has had a hemorrhage very recently, he had better go to an altitude by easy stages, for the sudden change may bring back the bleeding. The altitude treatment is not suited to cases of dry bronchitis, fibroid lung, emphysema, kidney disease, or some forms of heart trouble. In conclusion, he approved of the method of strapping one side of the chest where only one lung is affected, as a measure affording much relief to the patient and giving partial rest to the lung. In cases with pleural effusion, complicating tuberculosis, he did not consider it advisable to aspirate the chest, as the rule, on the ground that the lung should be kept as much at rest as possible. Where the straps have been worn for some time, he advised that they should be removed one at a time, at intervals of a day or so. He mentioned a case of pneumo-thorax that had been produced by coughing, after straps had been removed.

Dr. Miner, of Asheville, said that **Dr. Bridges** did not sufficiently differentiate his cases, in speaking of giving rest to the diseased lung. When he says that a diseased lung should not be exercised, the speaker took issue with him. The lung is not all diseased and the part not affected should be used. Part of the benefit of altitude is due to the increased expansion of the lung which it produces. The climate treatment is only an adjunct to the other treatment.

Dr. Moore, of Nebraska, said that a life in fresh air and sunshine are the curative agents that are most important, and that drugs and climate had little effect.

Dr. C. S. N. Hallberg said that with regard to creosote, great stress had been laid upon the necessity of the purity of the agent, and upon the value of the test which the lecturer relied upon. He informed the reader of the paper that creosote is not made in such simple method as that described, nor are the tests which he gave to be relied upon. Creosote is one of the most insoluble remedies, and is soluble only in 150 parts of water. It is fortunate that it is so, when such large doses are given. It is broken up in the intestinal tract into guaiacol and creosote and forms more soluble compounds. The greatest therapeutic benefit is to be obtained from doses no larger than 4 or 5 to 10 Gg., given in capsules or pill, which will pass through the stomach into the intestine, and be there gradually dissolved. A saturated solution (1½ percent.) has been advocated by **Dr. Hare,** for internal administration.

Dr. Klebs approved of the remarks of **Dr. Solly** upon the necessity of discrimination as regards the social and financial condition of patients. It has too often happened that patients are sent as far as El Dorado, to an altitude, and have nothing to live on when they get there. Such patients should be treated in hospitals or sanitarium.

De Lancey Rochester, of Buffalo, read a paper on "The Treatment of Pneumonia." Recognizing the disease as a form of acute infectious disease manifesting itself by septic intoxication, attended with a local disturbance in the lung and kidneys, he directed the treatment towards favoring elimination of toxins and excrementitious principles, counteracting the depressing effect of the poison upon the heart, and sustaining the strength of the patient. The bowels and skin are the avenues of excretion which should be stimulated. An initial dose of calomel (0.50 G) followed by a saline, not only opens the bowels, but relieves a distended right heart: it may be repeated when the indications of this condition present themselves. The hot mustard foot bath, followed by measures to obtain sweating, is also very useful, and may be repeated at four hour intervals during the disease. The diet should be fluid; a large quantity pure water should be administered.

For the heart, he advised strychnine (0.004 G every two hours), alcohol, or aromatic spirits of ammonia, given with liquor ammonii acetatis. Cupping or leeching of the affected chest, and in cases of over distension of the right heart, with increasing cyanoses, etc., venesection was advised. After venesection, or in cases of threatened heart failure, subcutaneous injection of normal salt solution may be resorted to. Oxygen inhalations may be required, where more than one lung is involved. Small doses of hypnotics, chloralania, chloral, or Dover's powder, may be required for sleeplessness. Digitalis in the early stages is irrational and unscientific. No abortive treatment is possible in an acute infectious disease. The serum treatment may prove to be the most scientific means of treating pneumonia.

Dr. W. L. Dickerson, of St. Louis, read a paper on "The Abortion Treatment of Pneumonia; a Plea for the Use of Cardiac Depressants in the Treatment of the Congestion Stage of Pneumonia;" in which he advocated the use of tincture of veratrum viride in small doses, every two hours, in the congestion stage of pneumonia, and reported most favorable results from this treatment in his own experience.

The discussion was a general one, participated in by **Dr. J. F. Spelman, of Anaconda, Montana;** **Moore, of Nebraska;** **Carlton, of Tennessee;** **Mary McCoy, of Duluth;** **Hawkins, of St. Paul,** and the Chairman. The trend of the remarks was in support of the position taken by the reader of the first paper and in opposition to that of the second.

THIRD DAY, THURSDAY. MORNING SESSION.

"The Influence of Certain Common Remedies upon Gastric Functions," was the title of a paper by **Boardman Reed, of Philadelphia.** He concluded that among dwellers in cities, perfectly normal stomachs are rare, especially among persons employed indoors. The indiscriminate administration of bitter tonics and of hydrochloric acid is capable of doing harm, to approximately normal stomachs, if kept up for even a short time. Hydrochloric acid (dilute), if given in cases of hydrochlorhydria, increases the acid secretion; it is injurious if given in hyperchlorhydria. Pepsin is of little value if given alone, if combined with hydrochloric acid, it aids weak digestive powers.

"The Treatment of Gastric Ulcer" was the subject of a communication by **Dr. Gustav Fuetterer, of Chicago.** The observation was made that the prognosis of gastric ulcer is less favorable than is usually believed, it is very slow in repair and may remain unhealed for months. Even after cicatrization has taken place the danger is not over, because it very frequently becomes the site of malignant disease. He advocated absolute rest, and for the first few days feeding with beef juice, from five pounds of beef daily, following this with milk diet for six weeks. The blood should be examined for its percentage of hemoglobin, and when this is below normal the beef-juice must be used until the normal rate is attained. The treatment is based on the dictum that ulcer of the stomach can form only when there is a certain amount of deficiency of the hemoglobin, and that it will heal when this deficiency is made up, by the beef-juice treatment. In cases of stenosis of the pylorus, early gastro-enterostomy is advised.

Dr. James B. Herrick, of Chicago, opened the discussion. He endorsed the statement that importance of gastric ulcer has been underestimated by the profession. Many cases terminate by hemorrhage, peritonitis, and pyloric cicatricial obstruction, or eventually become malignant. He spoke of the work of **Dr. Fuetterer** as deserving the highest praise, and approved of the method of treatment. Rest in bed with milk diet are essentials in the management. Small doses of morphine hypodermically not only relieve the pain, but favor the healing process by restraining the motion of the stomach.

A paper on "The Treatment of Gastric Hyperesthesia," was read by **Charles C. Stockton, of Buffalo.** The condition referred to was not a form of gastralgia and was not a symptom associated with hyperchlorhydria, but was due to exaltation of normal sensibility of the gastric mucous membrane, usually appearing in a neurotic patient. Indigestion does not exist although this condition might be mistaken for a symptom of indigestion. A positive diagnosis can only be made by exclusion and after a resort to gastric chemistry. In these cases, the slight pain or distress may be increased by taking food, and patients are often insufficiently nourished on this account. In some

the presence of free acid in the stomach, in any quantity whatever, gives rise to discomfort, which can only be relieved by alkalis. Any attempt to treat such cases as instances of hyperchlorhydria would lead to an aggravation of the symptoms. It is important, in the management, to increase the gastric tolerance and improve the nutrition by a carefully selected diet. Electricity is of signal service, with the negative pole in the stomach, and a current (5 to 10 ma.) of low voltage, used for five minutes, two or three times a week.

Hydropathic treatment, a cold douche or shower bath to the spine, the Scotch douche, and other hygienic measures, are as important as in the treatment of neurasthenia. Autacids are used symptomatically, and *mistura asafetida* may be given by the rectum. Dr. Tomkins, of West Virginia, said that mistakes are easily made in diagnosis of gastric disorders, and mentioned a case that had been pronounced carcinomatous by a specialist eleven years ago. The former is still living and in good health. He did not approve of gastric surgery, which he pronounced a crime, and physicians who send their patients to be operated upon for pyloric stenosis are *particeps criminis*. He advocated Fowler's solution in small doses, and some prepared foods.

Drs. Fuetterer, of Chicago; Osborne, New Haven; Johnson, Clinton, Iowa; Heinrich Stern, New York; McCoy, Duluth; Westbrook, of Indianapolis; Thomas McCrae, Baltimore; Dora G. Wilson, of Kansas City; Boardman Reed and Stockton continued this interesting discussion, which among other interesting features directed special attention to the great need of more knowledge of the principles of dietetics by the profession and especially of the prevailing lack of knowledge of the art of properly preparing food for both the healthy and the sick.

"The Theory and Practice of Organo-therapy," by S. Solis Cohen, was read by the Secretary.

"Acromegaly Treated with Pituitary Body," was the title of a paper by Sydney Kuh, of Chicago. The author insisted upon a connection existing between lesion of the pituitary body and acromegaly; in nearly all cases of this disease, sarcoma has been found involving the hypophysis. Some influence upon the growth of the body is excited by the pituitary body, where it is diseased, gigantism is produced; where it is atrophied dwarfing results. Exophthalmic goitre and acromegaly are associated so frequently as to make it unlikely that it is a mere coincidence. Powdered pituitary bodies having been employed in these cases of acromegaly, decided improvement was noted, especially in the headache. When the powder was stopped the headaches returned with their former intensity. In two cases decided nutritional improvement was noticed. While the treatment cannot affect the organic changes in the tissues, yet if the subjective symptoms may be relieved the treatment is of benefit, and deserves further trial.

"The Treatment of Graves's Disease with Thymus Extract," was the topic selected by John M. Dodson, of Chicago, for his communication. In several cases the author reported marked improvement in the classical symptoms of exophthalmic goitre following the use of powdered extract of thymus gland.

Discussion.—Dr. Osborne said that the papers had carried out his own idea that there is a connection between Graves's disease and acromegaly. In autopsies of cases of the latter disease the thyroid gland has also been found to be enlarged, in every instance. He had recently had two cases under the pituitary treatment at a dispensary, and had noted, by one, a remarkable improvement; the other case he was not sure of. The discussion was continued by Boardman Reed, the Chairman, the Secretary, D. Shelly, Kansas; Vaughan, of Ann Arbor, Stern, of New York, Kuh and Dodson.

"The Pharmacology of the Supra-renal Gland, and a Method of Assaying its Products," was read by E. M. Houghton, of Detroit, and was followed by one on "The Principle of the Supra-renal Glands," by Dr. Jokichi Takamine, of New York. There admirable communications well supplemented one another. Dr. Takamine detailed the efforts that had been made to discover the active principle of the adrenals previous to his own work upon the subject. Very recently he had succeeded in isolating a pure active principle, which possessed the power of raising the blood-pressure; this substance he had named "adrenaline." He described the method of separating it from the crude material of the glands, and demonstrated

several characteristic tests by which it can be recognized. A specimen of pure white, crystalline substance was presented and a review of its physiological effects given, with suggestions as to its therapeutic uses.

Remarks in commendation of these papers were made by Dr. Vaughan. Dr. Stern inquired if any cumulative effect had been observed from adrenaline?

Dr. Boardman Reed desired more information as to the poisonous effects, in single dose or after long administration.

Dr. Osborne asked with regard to its absorption by the skin and adaptability to hypodermic use. Drs. Vaughan, Dodson and Houghton also discussed the paper. A vote of thanks was tendered Dr. Takamine by the Section.

Officers for the ensuing year:

George F. Butler, of Chicago, Chairman; C. S. N. Hallberg, of Chicago, Secretary.

SECTION ON STOMATOLOGY.

In his annual address the Chairman alluded to the symposium of last year as having shown good results. It had brought advanced conditions to the schools and these advances were well recognized. We have a right to expect as an entrance condition a degree in letters. This is an age of progress. We need larger equipments for teaching. We must do everything as well as it can be done. Each investigator must in his own way solve all problems. We must never wait for the State Society to do it. Many important matters need solution. Some students have the happy faculty of solving whatever presents to them. But the expense is often too great for individual pockets. Hence such need aid in this particular and perhaps compensation for their work.

Dental examiners should not be appointed as a political gift. The best man should be appointed. A standard should be established by the National Association, then one who passes can go into any State to practice. Again, in the case of those who have practiced for years and are not fitted to pass an examination by absence from college, a certificate should be awarded. The department of prophylaxis is bright with possibilities; a fruitful field is here opening. One writer has shown the existence of bacteria on the teeth and a predisposition to the formation of a hard gelatinous film, a culture medium for micro-organisms. He calls it "gelatinous microbial plaque." These bacteria are malign or benign according to their environment. The saliva when abnormal is the exciting cause. Another writer tells of the active lives of bacilli from a superabundance of glycogen as found in the saliva making it alkaline, producing glucose, then lactic acid which unites with the lime of the teeth producing decay of the teeth. Other exciting causes are the improper nutrition in many cases. Another has proposed for the cleaning of the teeth a flat piece of orangewood for spaces between teeth used with pumice by which the teeth are thoroughly cleaned and polished. This also stimulates the vital functions. The use of fine salt once a week also will stimulate the gum tissue. Another subject of importance is the Dental Service of the United States Army. The plan proposed is not all we would like. We fortunately have Dr. Marshall as the President of the Examining Board. He is eminently fitted for the position. We should demand a high standard from Contract Dental Surgeons and this is well shown by the results of the fact that but two passed of fourteen applicants. He urges none to come up but those who are well prepared.

Science has made vast strides in Biology. We learn that protoplasm is not a single chemical substance, but highly complex and that continual chemical transformations occur. Protoplasm is supplied by the egg, hence the nitrogenous part is supplied wholly by the mother. While the nuclei are divided and from both parents are formed groups of chromosomes which are respectively paternal and maternal in their origin. Redivision takes place and so throughout the growth of the animal. Again an egg may be fertilized by chemical stimulus without the participation of the male element. Thus eggs of the sea urchin allowed to develop in sea water with a slight excess of potassic chloride develop an embryo slightly altered from nature. No skeleton is formed and larvae result, living, vigorous, but widely differing from the normal. Or lithium chloride in the water causes a more remarkable change, developing as new organisms. These processes cannot

redevelop and perish. These facts are interesting as thus creating new organic forms. Insects, frogs, etc. thus show that sex is determined by conditions of nutrition. We may yet succeed in fertilizing the egg by chemical means and produce males and females from analogous methods.

The second paper was by Dr. Wm. Carr, New York City, on the methods of appointment on boards of examiners. Diplomas should not give the right to practice. The low standard of schools is due to the lack of State supervision. License to practice should only be given after a careful examination by a Board of Examiners appointed by the State. Charters are granted recklessly by the Legislature, hence the teachers are not selected for merit. New York fortunately is not thus hampered, as the State Universities are the governing body. It has been seen that good colleges will endorse diplomas of bad schools outside the State. Even fraudulent papers were endorsed. Hence we should do away with diplomas. While there are Boards in nearly every State, yet as some refused to list all schools, litigation followed, causing great difficulty in the work of the Board. We can raise the standard in proportion to the demands of the profession. It is highly important that Boards are properly constituted of honest, competent men with eyes single to duty and then admission to the profession would be confined to the best, to the exclusion of the incompetent. Examiners must not be identified with teaching bodies, yet conversant with the arts of instruction and examination, able to frame questions which shall elicit from the candidates what knowledge they possess, and their ability to apply it. An appointment to this post should be regarded as an honor, never depending upon politics nor influence of any kind.

The third paper, Revenue for Conducting the Work of Boards of Examiners, whether by taxation of the people—by fees from the candidates—by taxation of the profession, was considered by G. I. Parmelee, Hartford, Conn. The effort is not to compel men to live up to a code but to protect people from improper practitioners. After carefully considering the subject, all points to the conclusion that revenue should be from the candidate, as in all other matters of similar character.

V. E. Turner, Raleigh, N. C., also considered the subject and concluded that the fees of candidates alone should be the source of revenue.

The next paper, The Dental College Standard, is it What it Should Be? If Not, What Improvements Should be Made? How May the Requirements be Made? Dr. C. Chittenden, Madison, Wis., said the standard is not the same in all States. Some demand a high education for entrance before graduation, eventually this will be adopted. By the colleges uniting with the Boards, it can be adopted at once. Make it impossible that matriculants can be given standing in any college on credentials, until these are passed upon by the State Superintendent and then by a joint conference of committees of the Colleges and Board. And if needed a probationary clause requiring all shortcomings to be made up without abandoning the study of dentistry. Once adopted, let all schools agree.

The next paper, by J. A. Libby, Pittsburg, Pa., on preliminary work. A college is chartered by the State for the purpose of educating students in specific branches as well qualified teachers, who are thoroughly earnest and loyal and who will see that only the competent are allowed to enter and who count the qualities of the student more than the profits of the school. This alone should be the rule, but unfortunately all are not so constituted. Funds are needed to pay expenses of the school. There should be a reform in the system of educating students. When this is realized laws will be adopted and the time hastened when the dentist will mean the worker in the mechanical part, and the name Stomatologist will take the place and he will rank as an M. D.

Alice Stevens, Chicago, read a paper, Infectious Diseases resulting from want of care in the use of instruments, especially syphilis of the mouth. Hence the need of proper and careful disinfection of all instruments used in the mouths, particularly of children. She explained how to recognize these affections as presented in the tooth cavity and the method of relieving them.

Dr. James G. Kiernan, Chicago, read a paper, Periods of Stress and their Dental Marks. He explained how the teeth showed these periods by their irregularities and markings, especially in the case of children who are borne by a mother during great trouble, etc.

Dr. Eugene S. Talbot, Chicago, presented Preliminary Work, introducing the symposium of degeneracy of the pulp, followed by Vida A. Latham, Rogers Park, Ill. Literature of the Pulp. Surgical Treatment of Cleft Palate, G. V. I. Brown, Milwaukee, and the section closed its work on Thursday with a discussion of Military Dental Practice, by John S. Marshall, Chicago. This section held as interesting and useful a session as perhaps any of the sections. We mention with much pleasure the continuation of its valuable Secretary, Dr. Talbot, in office, as this is the only way the work of a section can be maintained to its full standard.

SECTION ON HYGIENE AND SANITARY SCIENCE.

Dr. W. H. Heath, Buffalo, N. Y., presented a paper, State Supervision of Marriage, its possibility, scope, justification, possibilities. After demonstrating the necessity of the marriage license, and that the State is the proper power to issue this, proceeds to develop a modified special license which is more strict in its requirements than at present. He suggests that special certificates be issued showing the qualifications of the persons about to marry; as to health, issued by the physician; as to education regarding especially marital duties. This license not to be compulsory at the outset but issued to such able to meet the requirements. He proposes methods for educating the masses; as series of lectures in hygiene physiology, etc., of a popular character. He suggests inducements of various nature to contracting parties to fulfil requirements as for instance governments and municipal positions for themselves and offspring, etc.

In the discussion the general idea prevailed that this like many other schemes is visionary and perhaps premature.

Dr. W. T. English, Pittsburg, Pa., on Pulmonary Tuberculosis presented the idea that fear is concomitant with the pulmonary system up to the time of puberty. The very first respiration is due to a nervous impulse akin to fear. As adult life is reached this attitude toward the pulmonary system is changed to one of fearlessness and disregard. The author then comments on the fearlessness in tuberculous individuals and their friends. He contrasts the fearless and hopeful attitude of these with the apprehension of victims of carcinoma, etc. He suggests that the absence of this fear is detrimental to the effecting of cures and that it is the duty of the conscientious physician to instil into the mind a normal amount of fear for the good of the patient.

SECTION ON LARYNGOLOGY AND OTOTOLOGY.

JUNE, 1901.

This section convened in the Elk's Hall, June 4, 2.30 P. M., with Dr. John M. Mackenzie, chairman, in the chair, and a good number of members in attendance.

The Chairman's address was given by Dr. John M. Mackenzie, Baltimore, who digressed somewhat from the custom of former years in giving an address on "The Study of Laryngology in the University and in the Higher Medical Education," instead of reviewing progress in the specialties for the year past.

Dr. Mackenzie dwelt upon the importance of Laryngology and upon the neglect in teaching this branch in the Medical Schools of America as well as abroad, stating that the knowledge of this branch was a requisite for the degree in but one school in this country.

In speaking of Laryngology he included its sister specialties, Rhinology and Otolaryngology. He held that this branch should have a well equipped department and a full professorship in all first-class schools. He predicted that the laryngoscope was "going the way of the stethoscope and becoming the common property of the general practitioner of medicine, and that it would become an absolute necessity in internal medicine, and that a more general knowledge of Laryngology might have a salutary effect relegating to the rear that element whose only claim for special knowledge resides in the possession of the necessary apparatus which go to make up the armamentarium of the worker in this field."

The essayist carefully reviewed the development of the study of Laryngology and outlined the present excellent course in this branch in Johns Hopkins Medical School. He urged that the subject be looked upon by the student from the high vantage ground of general Pathology and laws of health and not from the level of a narrow special-

ist, and that there be more fraternity and co-operation among the different departments of medicine, and not until Laryngology becomes the inspiration of a higher effort and a loftier ideal would it reach the full fruition of its hopes.

The next paper read was on "The Treatment of Laryngitis," by Dr. O. T. Freer, of Chicago.

Dr. Freer holds that the metallic astringents are better than the vegetable ones, since they form a protective coat which limits the egress of secretion, hence the drying effect of these astringents.

This paper was discussed by Dr. Ingals, of Chicago, and several others.

The next paper was a very interesting report of four cases of Edematous Laryngitis by Dr. Jos. S. Gibb, of Philadelphia.

This paper was followed by some remarks on "The Total Extirpation of the Thyroid Gland," by Dr. G. F. Cott, of Buffalo.

The morning session, on June 5th, was opened by a paper on "Types of Membranous Pharyngitis," by Dr. W. E. Casselbury, of Chicago, which was discussed by Drs. Mayer, (New York), Shurley and Amberg, (Detroit), and Hollinger, (Chicago).

This was followed by a paper on "The Relation of the Middle Turbinate Body to the Chronic Nasal Diseases," by Dr. C. S. Baker, of Bay City, Mich., which was discussed by Drs. Barnhill, Casselbury, Ingals and Mayer.

Dr. J. H. Farrell, of Chicago, then read a paper on "Asthma as a Result of Nasal Condition," which was discussed by Drs. Jack, Casselbury, Amberg and Barnhill. Dr. Jack holding that there was no relation between Asthma and Nasal Conditions.

Dr. C. M. Cobb, of Boston and Lynn, then read a report from Dr. George Richards, of Fall River, of a case in which the styloid process was found embedded in the tonsil, after which he read a paper of his own on "The Effect which the so-called Catarrhal Diseases of the Nose and Throat have upon the General Health," in which he brought out the interesting point that rheumatic pains in distant parts of the body often disappear after thorough drainage of the diseased accessory nasal sinuses has been established.

This paper was discussed Drs. Casselbury, Woolen, Kline, Kuyt, Roy, Freer and Farrell, Dr. Casselbury stating that four cases of Anomalous Styloid in the tonsile had been reported to this section in the last few years, thus showing it was not an uncommon phenomenon.

At the afternoon session, June 5, the Nominating Committee reported the names of the candidates for Section Offices for the following year.

Dr. G. H. Makuen, of Philadelphia, was nominated for Chairman, and Dr. C. S. Barnhill, of Indianapolis, for Secretary. The nominations being closed, these two gentlemen were elected to fill the positions named.

The names of five members were then placed in nomination from whom two were to be selected to represent the Section in the new House of Delegates of the Association. Dr. Emil Mayer, of New York City, and Dr. George C. Stout, of Philadelphia, were chosen in this capacity.

Dr. E. Fletcher Ingals, of Chicago, then presented a most scholarly paper on "Empyema of the Frontal Sinus," which was freely discussed. This was followed by a paper on "The Anomalies of the Frontal Sinus and their bearing on the Chronic Sinusitis," by Redmond W. Payne, of San Francisco, Cal.

"New Growths in the Upper Respiratory Tract" were freely discussed after the reading of the following papers on this subject:

1. Carcinoma of the Nasopharynx, by Chevallier Jackson, of Pittsburg.
2. Sarcoma of the Nasal Passages with report of a Case, by Dunbar Roy, of Atlanta, Ga.
3. Epithelioma of the Upper Respiratory Tract, by S. A. Oren, of Illinois.

The afternoon session was closed with a paper on "Changes in the Facial Bones," due to Adenoids, by A. T. Mitchell, of Vicksburg.

Thursday morning session was devoted to a "Symposium on Mastoiditis," Dr. Stout being in the chair.

The first paper was that of Dr. E. P. Dench, of New York City, on "The Diagnosis and Treatment of Mastoiditis."

The second paper was by Dr. Hiram Woods, Jr., of Bal-

timore, on "Mastoiditis after Subsidence and without Recurrence of Tympanic Disease."

These interesting papers brought forth a general discussion, which was participated in by twenty members of the Section, the subject being thoroughly discussed in a most entertaining and instructive manner.

At the afternoon session on this day, Dr. G. Hudson Makuen, of Philadelphia, reported a case of an "Unusual and Interesting Tertiary Manifestation," after which the Section adjourned, after a most interesting program.

American Climatological Association.—The following delegates have been appointed to represent the American Climatological Association at the British Congress on Tuberculosis. Dr. Edward O. Otis, Boston; Dr. Judson Daland, Philadelphia; Dr. Henry L. Elsner, of Syracuse, N. Y.; Dr. Charles F. McGahan, Aiken, S. C.; Dr. Thomas D. Coleman, Augusta, Georgia; Dr. Carroll E. Edson, Denver. Dr. Guy Hinsdale, Philadelphia, has received a notice of his appointment as honorary member of Congress.

JOURNAL DES PRATICIENS.

April 13, 1901. (15me. Année, No. 15.)

1. Recurrent Intercostal Roseola. De BEURMANN and LOUIS DELHERM.
2. Enteroptosis. FRANTZ GLENARD.

1.—**Recurrent roseola** shows a tendency to appear along the posterior intercostal spaces, never appearing on the anterior surface of the thorax or abdomen. This has been seen in syphilis. As the eruption is fleeting, all syphilitics were examined twice weekly. Only eight typical cases were found among 1089 patients. Other varieties of roseola occurred, both circinate and ovoid. This eruption appeared in distinct lines along the intercostal spaces, each spot discrete, the whole resembling the branches of a tree, of which the spine was the trunk. The upper branches were shorter than those lower down. The eruption was visible from one to two weeks, being very distinct only a few days. The eight histories follow. As it lasted so short a time, it was probably not due to circulatory disturbance. It may have been due to syphilitic action upon the marrow, certain of Head's zones being affected. It recurs, is seen from the fourth to the sixth month of syphilis, is never serious, and yields to mercurial treatment. [M. O.]

2.—From a study of 40 autopsies, Glénard found that when the suspensory ligaments of the stomach and intestines are relaxed, with the descent of these viscera, stenosis will occur. But as the cecum has no suspensory ligaments, it alone will retain its normal shape. The result of the stenosis of the intestines will naturally be a diminution of the tension of the abdominal wall. Then the descent of the kidney or liver may follow. The subjective symptoms of enteroptosis are sudden pain in the right lumbar region, weakness, constipation, emptiness, dyspepsia, neurasthenia, emaciation, pallor, etc. The objective symptoms are tenderness in the right lumbar region, diminution in the abdominal tension, movable kidney, the colon felt as a cord, the cecum being normal in size, prolapse of the liver, epigastric pulsation, and perhaps plenoptosis and metroptosis. Saline laxatives are given, and sodium bicarbonate; suppression of all acids, wine, cereals, and fats; a milk diet ordered, then green vegetables, cold bathing, warm alkaline waters. First the intestinal, then the gastric or hepatic, finally the neurasthenic symptoms appear. An abdominal binder must be applied. The movable kidney is not due to corsets, but the constipation and enteroptosis are. This primary enteroptosis occurs commonly in women, with confinement or traumatism. Secondary enteroptosis is seen in men, due to gastric atony, probably hepatic in origin. For the liver plays an important role in all cases of secondary enteroptosis. Only after years of treatment do these patients recover their general health. Glénard employs his "belt-test" in the diagnosis of enteroptosis. The physician stands behind the patient, encircling the abdomen with the palms of both hands, supporting and lifting up the patient. If this affords relief, the diagnosis of enteroptosis is confirmed. [M. O.]

The Latest Literature.

BRITISH MEDICAL JOURNAL.

JUNE 18, 1904.

1. An Address on Theories of Inheritance, with Special Reference to Inheritance of Acquired Conditions in Man. J. GEORGE ADAMI.
2. The Pathogenesis of Tabes and Allied Conditions in the Cord. CHALMERS WATSON.
3. Case of Malignant Disease of the Lung, with Pseudo-Tuberculosis. H. BATTY SHAW.
4. Sequel to a Case of Pulmonary Hypertrophic Osteoarthropathy; Necropsy. E. FARQUHAR BUZZARD.
5. The Pulse-Rate in Pulmonary Tuberculosis. THOMPSON CAMPBELL.
6. The Position in which the Regurgitant Aortic Murmur is most clearly Audible at the base of the Heart. H. W. SYERS.
7. The Development of *Filaria Nocturna* in Different Species of Mosquitos. GEORGE C. LOW.
8. Notes on the Value of Experiments in the Question of Food Preservatives. A. S. GRUNBAUM.

1.—In his discussion of the theories of inheritance, Adami believes that the existence of hypothetical "ids" is absolutely disproved. It is to the germ plasm, the active matter in the germinal cells, and to the properties of the germ plasm, that we must turn in order to gain our basis for any sound theory of inheritance. This germ plasm it is which conveys living matter from generation to generation. Whatever life be, the fundamental phenomenon or possession of living matter is the performance of work coupled with growth. Growth is essentially a chemical process and any adequate theory bearing on the phenomena of growth must primarily be along chemical lines. The matter which is essential to, and directly concerned in, activity of any one species or individual is a single substance, which, following Nägeli, we can refer to as "idioplasm;" and our conception of the individual or of the separate cell units forming that individual must be that in each we have to deal with two constituents: the idioplasm, or essential and directive living matter and the cytoplasm, which is in the strictest sense non-living, or, certainly unable to exhibit the whole series of vital properties apart from the idioplasm, and which consists of various formed elements developed and influenced by the controlling idioplasm, intimately connected therewith, it is true, but at the same time not an essential part of the same. That the constitution of the idioplasm is not absolutely but only relatively constant has also to be assumed. Then we must admit that the idioplasm of the highest forms, judging from its powers of controlling and directing the development of highly complicated organs, is something very much more complex than the idioplasm of the unicellular organisms; that in the course of evolution this has undergone successive accretions of properties, and this accretion of properties is the manifestation and accompaniment of increasing complexity of constitution of that idioplasm. We can imagine a chemical substance so constituted as to be capable of modification in its molecular constitution—and so in sundry of its properties—without undergoing complete change, without other properties being lost. The mode of the atomic arrangement in the idioplasmic molecule may therefore in part explain the variation in the properties of that idioplasm seen throughout the animal and vegetable kingdoms. In the ovum there is one common idioplasm of simple type, to which when distributed in the various cells derived from that ovum, different side chains become attached, according to the relationships assumed by those cells, so that the cells of different orders are controlled and formed around protoplasmic or idioplasmic molecules composed of these central rings plus varying series of side chains. Indeed Adami is prepared to go further, and to state that the idioplasm possessing its full

complement of side chains must be regarded as *ipso facto* incapable of initiating cell multiplication. Fusion of the idioplasm of 2 individuals must be either a mere admixture or a true chemical combination. We may regard, then, the idioplasms from the 2 parent forms as undergoing a true chemical combination, the resultant idioplasm of the new generation being in truth a new idioplasm not possessing the identical properties of that of either parent, but being intermediate, tending in its characters and constitution towards the constitution of either one or the other, according, it may be, to the number or chemical activity of the molecules of one or other parent entering into combination. If the germ cells of both parents possess certain loosely attached or unstable side chains of more recent acquirement, which are of like nature, there is no sufficient reason why the protoplasm of the offspring should not also possess them. We can thus realize how it is that abnormal features present in both parents may be equally or more prominent in the offspring. Two orders of forces determine the structure of every cell in the body: (1) The previous influences acting upon its idioplasm and causing it to be of a particular constitution, and (2) the position in which the cell finds itself and the forces acting momentarily and immediately upon its idioplasm. Or, briefly, these 2 series of forces are inheritance and environment, and inheritance and environment determine the constitution of the idioplasm and the structure of the cells. Inheritance essentially depends upon the chemical constitution of the idioplasm or the life-bearing or biophoric protoplasm of the germ cells, not upon the number of the separate ids or biophores or ancestral plasms or pangenes contained in the idioplasm; and variation whether slight and individual or extensive, and leading to the production of species, is ultimately the expression of modification in the constitution of that idioplasm brought about by environment. This conception of the idioplasm with attached side chains, which are more firmly or more loosely attached, affords a perfectly adequate explanation of atavism and reversionary degeneration. We cannot conceive the direct transmission of identical lesions of this order from parent to offspring. Acquired disease and the effects caused by disease cannot in general be transmitted in such a way that the offspring presents lesions identical with those produced in the parent though it has to be recognized that there is the possibility of modification in that offspring due to the parental disease. We must recognize that constitutional disease, by leading to disturbance in the activity of important organs, tells not only directly upon these organs, but secondarily upon other organs—that it leads, for example, to altered condition of the blood, and so to altered nutrition of all the cells of the body. Among other cells, the germ cells may be directly affected, their idioplasm modified, and the offspring directly influenced. We can see evidences of direct transmission of acquired constitutional states. The toxins circulating in the blood of the individual undergoing immunization must also affect the germ cells; they must acquire immunity—and the individuals developed from them must have the same properties. As a matter of fact, this transmission of acquired immunity has been noted in rabbits which have been rendered immune to the *Bacillus pyocyaneus*. In those cases in which immunity is not developed, such as in chronic conditions like tuberculosis, we can comprehend how the toxins weaken the germ cells along the same lines as they weaken the general tissues of the body, and as the resistance of the body in general to a special micro-organism and its products becomes less and less, so also the idioplasm of the germ cells becomes less and less resistant, and so from parental disease the offspring gains a peculiar susceptibility to one special disease. If gout and the gouty diathesis are, as many hold them to be, of the nature of true autointoxications we are at liberty to regard the gouty diathesis as an example of truly somatogenic acquirement of an inherited and inheritable constitutional state. [J. M. S.]

2.—Watson believes that *tabes* is not a "nervous" disease in the sense usually apprehended, and that the lesions in and around the vessels are of primary importance, the lesions of the neurons being determined by local interference with the blood supply. There is good ground for the belief that the condition is dependent on a chronic auto-intoxication, the vascular lesions being to some extent general, but tending to be more advanced locally, and that the more advanced local changes determine a failure of nutrition in the adjacent nerve elements. The author had an opportunity of observing a horse affected with ataxia, paraplegia and a bilateral affection of the knee-joints of a nature not described in veterinary literature. The combination of clinical features led him to diagnose a lesion of the cord, most marked in the posterior columns, with associated neurotrophic joint lesions, of a nature akin to *tabes* in the human subject. The lesions found at the post-mortem examination were of a grosser and more widespread nature than had been anticipated, but the diagnosis was found to be substantially correct. The author describes the pathological appearances of a small piece of the cord from a case of *tabes* of 2 years' duration in a patient who died from malignant disease. Here also the evidence was confirmatory of the primary importance of vascular disease. The degree of vascular change was profound, and the degeneration of the nerve structures, as indicated by the amount of softening, was more acute than obtains in cases of uncomplicated *tabes*. He believes that in such a case we find additional proof of the general view of vascular disease as the primary factor in the **pathogenesis of *tabes*** as advanced in this paper. Given an added *toxemia* such as is present in malignant disease, the result will be an added severity in the local lesions throughout the cord, and these will be correspondingly greater in that part of the cord which is more susceptible to various toxic influences. In cases that run an acute course a careful investigation of the history will reveal the previous occurrence of conditions similarly capable of so influencing the tissues as to render them more susceptible to the influence of the toxins at work. Evidence can be adduced from the histological study of cases of advanced *tabes* in support of the view that the primary fault is to be found in malnutrition rather than in primary degeneration of the nervous elements. In specimens from a case of well marked *tabes* there were advanced degeneration of the posterior columns and slight involvement of the lateral tracts, diffuse degeneration of the cornu-commissural fibres, and decided marginal degeneration of the nerve fibers of the anterior part of the cord. The involvement of the cord was a very extensive one, and in the opinion of the author the changes in the various columns differ only in degree. The vessels in the affected areas were greatly thickened and the capillaries showed extensive thickening, with diminution of the lumen, sometimes to obliteration. The space in some cases were mere dilations of lymphatic spaces, determined by traction of the surrounding cirrhotic tissue, and in others they represented spaces from which nerve fibres had disappeared. The nature and extent of these changes indicated vascular diseases as the primary disorder. More especially is this the case when it is remembered that disease of the vessels induced by the long-continued action of some irritant will cause defective nutrition of the related cord, and that defective nutrition accounts simply and adequately for degeneration of the nerve fibers. We find in the grey matter a varying degree of overgrowth of neuroglia. This is precisely the condition that occurs in the cells of the grey matter in the cortex in general paralysis, which is associated with, and indeed, dependent upon vascular changes in the smaller vessels supplying the affected areas. The author referred to the case of a man who was suffering from *tabes* and in whom previous illnesses afforded good grounds for thinking that his general powers of resistance to all toxic agents might be materially lowered. This was especially true of the digestive tract. The life of the patient and his dietetic habits were specially favor-

able to progressive diminution of the natural powers of resistance in the gastrointestinal mucous membrane. The initial symptoms which extended over a year, were directly referable to the digestive tract. The continued fetor of the patient's stools and melenia in the intervals between the paroxysms, indicated to the writer the primary importance of the intestinal lesions. During the gastric crises the patient presented a slightly pathological leukocytosis characterized by polymorphonuclears 88%, lymphocytes, 11%; eosinophiles, 1%. Watson thinks it possible that the crises are of a nature akin to relapses in some recognized infective conditions, the difference being merely one of degree. Anomalous cases are most readily explained by the vascular theory of the origin of the disease.

This theory will also readily explain the relationship between the onset of the disease and traumatism, exposure to cold and the like; the causal relationship between *tabes* and heart lesions; the cases of tabetic ecchymosis; and the great variety of clinical features seen in advanced cases. The broadest conclusion that we can deduce concerning the relation between *tabes* and syphilis is that syphilis alters the physiological condition in such a way as to favor the attack and operation of the actual cause of *tabes* and allied conditions. In this respect the influence of syphilis is similar to that of measles or scarlet fever in leading to the development of tuberculosis, and similar also to the action of the influenza bacillus in relation to other pathogenic organisms. The proper line of investigation concerning the pathogenesis of *tabes* is directed to the discovery of the nature and source of the toxic substance at work. The alimentary tract furnishes the chief area of investigation, and, in all probability, it will be proved to be the original source of the *toxemia*. [J. M. S.]

3.—Shaw reports the case of a man, aged 27 years, who suffered from pain in the left side of the chest, shortness of breath, and weakness, for 4 months. The disease began suddenly in an attack of what was considered to be influenza; ultimately "pneumonia and pleurisy" developed. On admission to hospital, the patient was distressed in breathing, and had a short spasmodic cough, which caused considerable pain in the left chest and which was accompanied by a copious, frothy expectoration. There was considerable flattening at the left apex, and, on the same side, the vocal fremitus was weak and the percussion note in the lower part of the axilla was dull, though a skodaic note was obtained at the apex. The breath sounds on the left side were very weak, more especially at the base. The temperature was 103.4°, pulse 100, and respiration 36. Fifteen days after admission the patient's condition suddenly became much worse; he coughed up about half a pint of very offensive, purulent material, had great dyspnea and cyanosis, and died a few hours later. The pathological diagnosis made at autopsy was **sarcoma of the root of the left lung**, producing stenosis of the bronchus and the vessels, and associated with pneumonia, probably due to the septic organisms present. The lung condition closely resembled that met with in tuberculosis, with the exception that the process was more marked at the base than at the apex. [J. M. S.]

4.—Buzzard referred to the case of a patient who was suffering from a typical form of pulmonary hypertrophic osteo-arthritis which was published in the *British Medical Journal*, 1913. The patient had a history of cardiac failure. At the necropsy the skull was found considerably thicker than normal, and the bones were very hard and dense. There was edema of the brain; the pituitary body was soft and a little purulent material appeared to escape from it. There was a marked curvature at the level of the third and fourth dorsal vertebrae. An abscess cavity situated at the root of the right lung opened into the spinal canal from the front, but the whole of the disease lay outside the dura mater which was covered with thick granulations. The cord presented a somewhat softened appearance at the level of the disease. No changes could be found in the internal aspect of the left wrist joint, but examination of the ends of the ulna and the radius showed

them to be thicker than normal, the increase in thickness affecting the dense bone more than the cancellous. Ascending and descending degenerations could be seen in sections of the spinal cord above and below the lesion in the upper dorsal region. The median, ulnar, anterior crural digital and sciatic nerves presented no degenerated fibres. There were no appreciable alterations in the bones or joints of one finger. The lungs showed marked thickening of the pleura and a very fibrotic condition of the pulmonary tissue, but no tubercles or definite caseation. Sections of the pituitary body showed chronic inflammatory change but no tubercles. [J. M. S.]

5.—The question that an examining physician to a sanatorium for tuberculous patients is called upon to decide is: Can recovery or an approach to it be reasonably expected after treatment of the patient for 6 months? After a careful consideration of the extent of the disease, as evidenced by the physical signs, and the acuteness of the process indicated by the course of the temperature, due regard should be paid to the pulse. Having noted the rate when patients presented themselves for examination prior to admission, and compared it with the record obtained during a week's confinement to bed Campbell finds that on an average there is a decrease of 20 beats per minute in the latter case, the difference being naturally smallest when there has been the least departure from the normal rate in the first instance. Thus to form a true impression of the vital powers in the case of a phthisical subject presenting himself in the consulting room, 20 beats can, on an average, be subtracted from the pulse-rate observed during the examination. If, on making this allowance, the pulse-rate exceeds 100, the case is not likely to exhibit an approach to recovery in the time mentioned above, and is therefore not suitable for admission. In the case of patients under more direct observation, if, after a period of complete rest in bed, the pulse continues to run at or exceed 100 outlook is not promising. In cases of tuberculosis complicated by mitral stenosis, a pulse-rate exceeding 100 is not of much grave import so far as the tuberculous process is concerned. In attaching a significance to the pulse-record in cases of pulmonary tuberculosis, allowance must be made for the possibility of over-exertion, excitability under examination and the presence of mitral stenosis; but, with these reservations, some assistance will be obtained in making a pronouncement regarding the probable duration of life. [J. M. S.]

6.—Syers holds that in at least 95% of the cases in which aortic reflux occurs the diastolic murmur is heard much more loudly at the second left interspace close to the sternum than in the second right interspace. This undoubtedly accounts for the fact that aortic reflux murmurs are constantly overlooked. The mistake has arisen partly in the growing tendency to employ the binaural instrument. [J. M. S.]

7.—Will be treated editorially.

8.—Grünbaum criticises the conclusions of Rosenheim and Tunncliffe concerning the influence of boric acid and borax upon the general metabolism of children. Only 3 experiments were made. Obviously very little weight can be attached to negative results of 3 experiments even if they are all concordant, especially since positive results of injury are on record. The period of administration was only 12 days. This is rather a short time from which to draw general conclusions. The age of the children varied from 2½ to 5 years—that is, well over the age in which milk usually forms the only article of diet, and the age at which the alimentary canal is most sensitive. But the mere fact that the metabolism remained practically unaltered is not *per se* evidence that the boric acid compounds caused no injury. Boric acid, as well as borax, has a distinctly inhibiting effect on the rennet ferment if added in proper solution. Although it is correct that no erythematous rashes have been recorded through taking borax with food the authors have omitted to mention the far more

important fact that other more serious toxic effects, which could hardly have been due to anything else, have been recorded as the result of taking milk drugged by the dealer with borax. The quantities of borax given were certainly much less than that required to inhibit bacterial growth in milk and less than required to preserve milk for 24 hours in summer. It is impossible to judge from an experiment of 2 or 3 weeks' duration whether taking a drug over a lengthened period, especially in infancy, may not affect the length of a man's life. There is no reason to suppose that any ordinary organic or inorganic substance which will injuriously affect a cell like a bacterium, does not also injure the cells of the alimentary canal. The specific antitoxins and similar bodies are of course exceptional. The repair of these injured cells throws a strain on the organism which it would not have had without the addition of the preservative to the food. The fact that the commonly employed antiseptic preservatives are rapidly eliminated by the kidneys, either unchanged or only slightly changed, is, to the author's mind, the most conclusive evidence of their poisonous character. It throws an uncalled for burden on the normal kidney, and when the kidney is no longer normal, may be positively dangerous. [J. M. S.]

LANCET.

June 1st, 1901.

1. A Clinical Lecture on Acroparesthesia, Erythromelalgia, Sclerodactylia, and other Angio-neurotic Disturbances, etc. THOMAS D. SAVILL.
2. Arterial Hypertonus and Arterio-Sclerosis; their Relation and Significance. WILLIAM RUSSELL.
3. The Bacteriology of Sporadic Cerebro-spinal Meningitis. WILLIAM HUNTER and ALEXANDER W. NUTHALL.
4. On the Operative Treatment of Corneal Astigmatism. A. BREUER.
5. A Further Note on the Technique of the Quantitative Estimation of the Bactericidal Power of the Blood, etc. A. E. WRIGHT.

1.—Savill delivered a lecture at the West End Hospital for Diseases of the Nervous System, on acroparesthesia, erythromelalgia, sclerodactylia, and other angioneurotic disturbances. The author defines acroparesthesia, as a symptom, characterized by tingling and numbness, and occasionally by redness and swelling of the hands and feet. This condition is frequently associated with such conditions as general paralysis, tabes dorsalis, or gastric disturbances, but may occur without these morbid states. The main features of the disease, erythromelalgia, are painful redness, and swelling of the extremities. The term sclerodactylia is defined as meaning a localized form of scleroderma affecting the fingers and toes, and occasionally the ankles, legs, wrists, and fore-arms. He contends that these conditions are undoubtedly related to Raynaud's disease. He believes that acroparesthesia and erythromelalgia are probably closely allied with Raynaud's disease, and during the past two years the author has met with some thirty-five patients presenting more or less definite symptoms pertaining to this class of diseases. After giving a report of a number of cases, Savill suggests the following clinical classification of vaso-motor disorders of the extremities: (1) *Vaso-dilator disturbances*, (a) the early chronic stage being characterized by attacks of redness, tingling, and burning (*congestive acroparesthesia*); (b) the late chronic stage is characterized by permanent swelling (*erythromelalgia*); (c) Should these conditions be acute, the symptoms go on to gangrene (*congestive or asphyxial type of Raynaud's disease*). (2) *Vaso-constrictor disturbances*, (a) the early chronic stage being characterized by pallor, numbness, and tingling of the extremities (*ischemic acroparesthesia*); (b) the late chronic stage is characterized by thickening of the skin and subcutaneous tissues (*sclerodactylia*); (c) If these conditions should be

come acuae dry gangrene probably results (syncopal type of Raynaud's diseases.) [F. J. K.]

2.—Russell read a paper before the Medico-chirurgical Society of Edinburgh on May 1, 1901, on "The Relations and Significance of Arterial Hypertonus and Arteriosclerosis." The author gives an account of the literature of this subject and his personal observations. He contends that recurring or continued hypertonus is finally followed by hypertrophy of the muscular media of the arteries.

3.—Hunter and Nuthall discuss the bacteriology of cerebro spinal meningitis. They give a report of ten cases and conclude that a diplococcus was found in the cerebro-spinal fluid of all the cases. Morphologically and biologically this diplococcus was identical with Weichselbaum's diplococcus intracellularis meningitidis. In some of the cases bacillus influenzae and the bacillus of tuberculosis were associated, while in others the diplococcus was found in pure culture. The clinical and pathological manifestations, found in the cases they analyzed, were identical with those of the so-called posterior basal meningitis. They suggest that posterior basal meningitis is probably a sporadic form of cerebro spinal meningitis due to the diplococcus intracellularis meningitidis. [F. J. K.]

4.—Breuer has obtained good results from cauterization in corneal astigmatism. He selected only such cases for operation in which there was a reasonable chance that the patient could be left without glasses afterwards. The operation was therefore confined to cases of mixed astigmatism and compound hypermetropic astigmatism, the best results having been obtained in the latter cases. An over-effect should always be produced, and according to the author the part which is lost seems to be less in adults than in children. The more superficial and peripheral the cauterization, the better chance is there for the result to disappear in time. But if cauterization extends through one half the thickness of the cornea, a permanent result will ensue. He advises the operation in cases of compound hypermetropic astigmatism of high degree. He employed the ordinary loop of fine platinum wire connected with the electric main, (alternating current) by a transformer and rheostat. The author employs red heat and produces a small punctate burn in the limbus of the cornea or in the cornea itself, penetrating about one half the thickness of the cornea. The cauterization is performed under local anesthesia. [M. R. D.]

5.—Will be treated editorially. [F. J. K.]

MEDICAL RECORD.

June 15, 1901.

1. A Note on the spread of Yellow Fever in Houses. Extrinsic incubation. H. R. CARTER.
2. On the Origin of Cancer: What Remains to be Demonstrated. SAMUEL W. BANDLER.
3. The Redundancy of the Preinsula in the Brains of Distinguished Educated Men. EDWARD A. SPITZKA.

1.—H. R. Carter discusses the extrinsic incubation of yellow fever. He mentions instances in which patients visiting infected houses long after the disease is supposed to have disappeared, have suffered from attacks of yellow fever. Carter concludes that the intervals between the infecting cases, and the first and secondary cases are habitually, considerably greater than the period of incubation of yellow fever. Yellow fever is then not contracted in any of these houses by those residing continually in them until a considerable time (in days) after the development of the infecting cases, although these same inmates had contracted the disease in the same houses. Later cases of yellow fever which occurred aboard ship after detention at marine and quarantine stations have not been followed by others among the crew. Cases of yellow fever which occur

in houses disinfected soon after were not followed by other cases among the inmates. Cases of yellow fever which occurred in houses vacated soon after, have not been followed by other cases from inmates leaving, although cases occurred among those who remained in the houses or neighborhood. Cases of yellow fever which occur in clean houses, are not often followed by other cases among the inmates exposed to no other infection until after such time as shows that the disease was not contracted for a number of days after the development of the first case, although the same inmates had developed yellow fever from these same houses later. It is evident that a knowledge of the interval in a sufficient number of instances, is sufficient to determine approximately the usual period of intrinsic incubation. He concludes that from 10 to 17 days after the development of the infecting case seems to be about the usual limits for contracting the disease by the first of the secondary cases when there are many of such cases in a house. This determination of the period of intrinsic incubation is an approximate one only. [T. L. C.]

2.—Samuel W. Bandler, apropos of the Gaylord's work on the origin of cancer, touches upon some of the investigations which have been made in this field. Leopold's results are expressed in the following chain: 1. In the fresh ovarian carcinoma of a certain patient were found blastomycetæ. 2. From this fresh carcinomatous tissue a pure culture of blastomycetæ was obtained. 3. This pure culture, injected into the testicle of a rat, produced a large number of peritoneal nodules (but not carcinoma) causing the death of the rat, and in the fresh as well as in the hardened tissue were a large numbers of blastomycetæ. 4. From these nodules a pure culture of blastomycetæ was obtained. If we are successful, on inoculation of this last pure culture into rats, in producing in them again neoplasms which are of such a character that they produce death of the animal, then the ring is complete and no doubt can be well entertained that blastomycetæ are able to produce malignant neoplasms. The causal relation of blastomycetæ to the growths produced in animals by Leopold must be granted. The decision concerning the character of these neoplasms and their actual relation to carcinoma and sarcoma is to be the controversial point. [T. L. C.]

3.—Edward Spitzka discusses the redundancy of the preinsula in the brains of distinguished educated men. The insulae of the human brains are of fundamental importance in the interpretation of mental stages. The writer was afforded exceptional opportunity in the study of the brains of the Sequins (father and son), with particular reference to a region whose development is related to that of the regions to which the faculty of speech is referred. In the brains of Dr. Edouard Sequin and his son, Dr. Edward C. Sequin, the left preinsula is exposed. The appearances of the brains are quite indicative of high intellectual capacity nor are the opercular regions in the least defective, though they fail to come into typical apposition on the left side. The explanation of this anomaly is corroborative of Waldschmidt's report upon the brains of the two Professors, namely, that the left preinsula is better developed than its fellow on the right side. So great is this development in the two brains under examination, that the left preinsulas are virtually thrust aside the opercular parts and made itself visible. Spitzka's conclusions are that in the highly intellectual (for example the two Sequins) owing to the excessive growth and development of the left preinsula causing a displacement of the opercula thrusting them apart, as it were, even though the latter be very well developed. In the defective, exposure of the preinsula is due to deficient development of the opercula and because these fail to approach each other. In such cases the insula itself is without a single exception in the series studied by this writer, of inferior development, indicated not only by the soundings of the Sylvian cleft, but also by the flatness of configuration, and lesser area of the insula cortex. [T. L. C.]

NEW YORK MEDICAL JOURNAL.

June 15, 1901. (Vol. LXXIII, No. 24).

1. An X-Ray Study of the Causes of Disability following Fractures Involving the Elbow Joint. SAMUEL LLOYD.
2. A Modified Urethral Dilator-handle. FERD. C. VALENTINE.
3. Hyperacidity (Superacidity, Hyperchloxydria, Superaciditas Chlorhydrica). A Clinical Study. H. ILLOWAY.
4. Penetrating Wounds of the Abdomen. RUSSELL S. FOWLER.
5. Paramyoclonus Multiplex. L. J. MORTON.
6. A Case of Cerebellar Apoplexy, with Autopsy. LEONARD WEBER.

2.—The advantages put forth by Valentine in his article on **modified urethral dilator-handle** are the following: (1) While being guided by the amount of resistance for each increase of dilatation, the dial is continually under the operator's eye, positively guarding against any excess of dilatation and making any change of position unnecessary; (2) Having no dial or shield at its sides, this modified dilator is more easily introduced and more easily held in position during its employment; (3) The dial, being beyond the patient's range of vision, offers him no inducement unnecessarily and even dangerously to increase its calibre; (4) The improved mechanism of this dilator-handle simplifies the construction of the instrument without increasing its cost. [T. M. T.]

5.—Morton describes **paramyoclonus multiplex** as a spasm of several muscles of the face, neck, arms and lower limbs, as well as of the muscles of the trunk. The muscles of the hands and feet are not involved. The spasms are clonic and are usually symmetrical and at times more violent than at others; the contractions vary in violence and frequency, the latter from five to fifty minutes. The external muscles are most frequently involved. This kind of tremor, with the shifting and varying forms of contraction, does not always render a diagnosis easy. [T. M. T.]

MEDICAL NEWS.

June 15, 1901. (LXXVIII, No. 24).

1. Decortication of the Lung for Chronic Empyema. GEORGE RYERSON FOWLER.
2. A Study of Some Complications and Sequelae of Typhoid Fever. H. A. HARE and H. R. M. LANDIS.
3. "The Porro-Cesarian Operation," with Report of Two Successful Cases. JAMES H. GLASS.
4. The Treatment of Scarlatinal Nephritis. CHARLES GILMORE KERLEY.

1.—In his article on **Decortication of the Lung for Chronic Empyema**, Fowler gives the following conclusions: (1) Decortication of the lung is an operation adapted to all cases of old empyema in which extensive and pre-operatively discoverable tuberculous lesions of the lungs are not present, and in which the patient's condition will permit of a major operation; (2) It may be advantageously substituted for Estlander's operation in the majority of instances in which the latter has been considered, up to the present time, as being indicated, since it is more a rational procedure in that it combines the advantages of restoration of function of the lung, so far as this is possible, with closure of the empyemic cavity; (3) It should replace Schede's operation in all cases; (4) The method of extirpation of the diseased portion of the pleural membrane, including the visceral, cortical, and diaphragmatic portions, is the operation of choice; (5) Failing this, visceral pleurotomy should be selected; (6) Pleurotomy, with simple detachment of the visceral layer of the diseased pleural membrane, gives sufficiently good results to warrant the surgeon in resorting to this procedure in cases in which the condition of the patient will not permit the application of the other and more desirable methods; (7) Whatever operative method is adopted, as complete access to the cavity of the chest as possible should be obtained, and rapid closure of the opening in the chest-wall secured, since the complete re-expansion of the lung must depend largely upon the normal respiratory movements; (8) Pulmonary or respiratory exercises should not be neglected in the after-treatment, since these aid greatly in the restoration of the function of the lung. [T. M. T.]

2.—Hare and Landis, in their paper on **Some Complications and Sequelae of Typhoid Fever**, take up the various interesting facts as follows: (1) Typhoid Fever in Pregnancy; (2) Typhoid Fever in Children; (3) Symptoms in Children; (4) Temperature in Children; (5) Eruption in Children; (6) Circulatory and Nervous Symptoms; (7) Mildness of Onset; (8) Abrupt and Severe Onset; (9) Chills; (10) Abortive Type; (11) Alimentary Symptoms at Onset; (12) Respiratory Symptoms at Onset; (13) Nervous Symptoms at Onset; (14) Renal Lesions at Onset. [T.M.T.]

3.—Glass gives the following indications for the **Porro operation** as formulated by Howard A. Kelly: (1) Where there is good reason to anticipate sepsis, where, for example, the patient is exhausted from protracted labor, and where manual or instrumental efforts at delivery have been made repeatedly or without due antiseptic precautions; (2) Where there is cancer of the cervix uteri; (3) Where the uterus contains myomatous tumors which block the pelvis or which cannot be safely removed by myomectomy; (4) Where there is an extensive atresia of the vagina; (5) Where there are bilateral ovarian tumors and no sound part of an ovary can be found and left; (6) When hemorrhage from the placental site is uncontrollable. [T.M.T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

June 15th, 1901.

1. Internal Medicine in the Nineteenth Century. N. S. DAVIS.
See Philadelphia Medical Journal, Page 1120. June 15, 1901.
2. Some Observations on Chronic Seminal Vesiculitis. ARTHUR L. CHUTE.
3. Iodophilia. THEODORE DUNHAM.

2.—Chute and O'Neill found 60 cases of **seminal vesiculitis** among 540 out-patients presenting various sorts of genito-urinary disease in a clinic that has a wide reputation among gonorrheal patients, but in which syphilis is not treated. The symptoms of seminal vesiculitis may be divided, perhaps rather artificially, into the direct and the reflex. Among the direct symptoms are feelings of vague discomfort in the rectum and perineum, which at times become actual pain and discomfort on defecation; persistence of discharge or shreds, in patients in whom stricture and other gross urethral lesions can be ruled out; the persistence of small comma-shaped shreds from the prostatic urethra; the recurrence, without any indiscretion on the part of the patient, of a urethral discharge which had nearly or quite stopped; frequency of micturition sometimes associated with more or less tenesmus; nocturnal emissions slightly streaked with blood, and the persistence of mucoid discharge from the glands of the urethra. The reflex symptoms comprise all the symptoms more commonly ascribed to sexual neurasthenia. The most characteristic symptoms of seminal vesiculitis are the occurrence of irregularities in the function of erection. In the early stages of the disease it is common to have a great increase in sexual desire, which in later stages gives way to sexual apathy and impotence. Absolute diagnosis can only be made by rectal examination. The examination should be made with an empty rectum and a moderately full bladder; the patient should stand with his feet apart, bending well forward over a chair, and his legs should be straight at the knee. The examiner should make suprapubic pressure with his hand or closed fist so as to crowd the pelvic viscera down so that the vesicles are more accessible. When the vesicles and ducts are diseased, they are enlarged and hard to the touch, and the patient complains of tenderness when they are palpated. In other cases one feels nothing, and the examination will show only unilateral or bilateral tenderness. Various irregularities in the contour and consistency of the prostate may be made out. After massage the material that drips from the meatus during the stripping process is milky and, on immediate examination of its contained detritus, if all the spermatozoa are non-motile it is a pathognomonic sign of vesiculitis. Non-motile spermatozoa in the detritus washed out by the urine is not decisive. The urine voided after massage is usually more or less turbid, with a slightly opalescent tint, and in it there are often little caseous-looking masses which are heavy and fall to the bottom of the glass. These are made up of epithelial and pus cells, and frequently contain large, partly-rolled plates

of mucus. The treatment that yields the best results includes massage of the prostate as well as of the vesicles and ducts. Massage should be performed by the terminal phalanx of the right forefinger, which should gently stroke the diseased tissues in a downward direction. At first the patients are massaged at intervals of from 5 days to a week. Later, the intervals are longer and the massage more thoroughly done. If the patient has emptied his bladder and cannot pass urine after massage it is wiser to fill his bladder with mild corrosive sublimate permanganate or nitrate of silver solution, and then allow him to pass it. In a few instances a mild cystitis has followed massage when the refuse has not been washed out at once. When the disease has been of long duration dilating seems to have a beneficial effect. Hot rectal irrigations through a double current tube, tonics and hygiene are useful accessories to the treatment. To allow sexual intercourse occasionally when the treatment is pretty well advanced seems probably not harmful, but to advise it as a therapeutic measure is a great mistake. [J. M. S.]

3.—Dunham uses a solution composed of 3 parts potassium iodide and 1 part of iodine in 100 parts of water, which is thickened to a syrupy consistency by the addition of lumps of gum arabic. The blood smear, prepared in the usual way, is mounted in a drop of this syrup. The lymphocytes and the eosinophiles are not affected by the stain. In normal blood, the polymorphonuclear neutrophiles are either unaffected or their protoplasm is tinged a faint pinkish or brownish color. Under some pathological conditions the protoplasm of a certain proportion of the polymorphonuclear neutrophiles takes on a reddish-brown color; in some it is a diffuse stain, in some a granular net-work, while in others the color is confined to a large or small refractive granules, varying in tint from a light pink to a dark red. When one or more such leukocytes can be found in a search of a few minutes we have the condition which, for the sake of brevity, the author calls "idiophilia." The condition is apparently always present in progressive suppurations and in progressive pneumonias. In acute suppuration the intensity of the reaction is said to be closely related to the intensity of the process. In cases of so-called tuberculous abscess the reaction is absent. Abscesses caused by the germs of acute suppuration, but which are well walled off and have assumed an indolent course, rarely give the reaction. In 2 cases of pneumonia the reaction appeared before physical or other signs were especially suggestive of that disease. [J. M. S.]

1.—In an address delivered before the Society of Internal Medicine at Chicago, Osler discusses the natural method of teaching the subject of medicine. He groups the studies

in a medical school into three classes. The first pertains to the mechanism of the normal body; the second, to a study of the abnormal; and the third, to a study of prevention and rectification of deviations from the normal. The department of medicine at the Johns Hopkins Hospital consists of a professor, who has charge of the medical department of the Hospital, an associate professor, instructors, and assistants. The medical staff is composed of eight resident physicians. The four senior residents are actively associated with the teaching. Preliminary instruction in physical diagnosis is given in the second year by Dr. Thayer, the associate professor in medicine. The third year students are taught chiefly by observation. They are given courses in physical diagnosis, clinical microscopy, practical work in history-taking, and attend the general medical clinic. Much attention is directed to the observation class. This class attends the out-patient department at 12 o'clock, three days of the week. The third year student is required to devote two hours twice per week to the study of physical diagnosis and clinical microscopy. Special attention is directed to the teaching of history-taking. The third class participates actively in the general medical clinic. The student of the fourth year serves as a clinical clerk in the medical wards for two months. This instruction is given from 9 to 11 every morning. Dr. Osler's criticism as to the ward work, is that the term is too short, suggesting that at least three or six months should be devoted to this particular study. Dr. Osler meets the clinical clerks for an hour or two once a week in order to discuss the events of the week. The senior students attend the general clinic. Recitations are also held in the fourth year. [F. J. K.]

2.—Will be treated editorially. [F. J. K.]

3.—Campbell discusses gumma of the spermatic cord, reviews the literature, and gives a report of a case. In 1890 the patient had a chancre which was followed by many of the secondary lesions of syphilis. When the patient first presented himself, in 1897, he was suffering from ulcerating gummata of the legs. After a course of treatment the lesions disappeared, and in August, 1899, he complained of a swelling about the size of an almond which was located just outside of the right external abdominal ring. The swelling disappeared after treatment with potassium iodide and mercury. [F. J. K.]

4.—William H. German discusses the question of surgical shock referring first to its indefinite pathology. The author inclines to the theory that shock is due to the irritation of peripheral ends of the sensory and sympathetic nerves and a general functional paralysis of the nerve centers causing a disturbance of respiratory and circulatory action. The two forms of shock and the shock with excitement are described and illustrated by cases. The author shows that the same injury will in one subject produce torpid shock and in another produce prostration with excitement. The author thinks it difficult to account for death occurring several days after injury or operation from shock which has not manifested itself until this time. He thinks that in most instances some other cause for death can be found. A case is reported of death from fat embolus. [J. H. G.]

5.—J. F. Pritchard urges upon the profession the use of non-constricting dressings in fractures and condemns strongly the use of plaster-of-paris as a preliminary dressing. [J. H. G.]

6.—H. N. Rafferty reports a case of acute glaucoma developing in a cataractous eye, after cataract extraction in the other eye. Iridectomy and cure. A 53-year-old male developed acute glaucoma in the right eye 53 days after cataract extraction in the left eye. The latter was performed without any pressure on the eye ball and without capsulotomy, the lens escaping intact, which was explained by the author as probably due to the over-ripe and atrophied condition of the lens and to an absence of adhesions of the posterior capsule to the lenticular fossa. After the

paracentesis of the anterior chamber, a broad peripheral iridectomy was performed, resulting in the disappearance of the pain. [M. R. D.]

7.—Einhorn read a paper before the New York Academy of Medicine on May 16, 1901, on "**Stitophobia of Enteric Origin.**" The author defines sitophobia as meaning "fear of food." He uses the term sitophobia only for those conditions which result from bad consequences in mentally sound people, and excludes the cases which occur in the insane. He uses the term "sitophobia" as meaning "fear of food," when due to some intestinal disorder. He gives a report of three cases and remarks that sitophobia of moderate degree is of common occurrence. The author discusses the treatment of this condition, mentioning that it is important that the patient should be made to eat sufficient quantities of food. The bromides in nervous conditions, and codein in painful affections are the most valuable medicaments. [F. J. K.]

8.—Heman H. Brown discusses the anatomical relations of the **conjunctiva** with the nose and calls attention to the fact that in treating conjunctivitis one is not treating an isolated structure. He calls attention to the importance of recognizing the association of diseases of the **conjunctiva** and the **Schneiderian** membrane. [M. R. D.]

9.—Gilliam claims that all **suspensions of the uterus** of whatever kind are makeshifts and that anchorage of the uterus by means of the round ligaments is the nearest approach to the ideal. As a choice between evils the round ligament suspension is superior to all others, both from a physiological and from a utilitarian standpoint. He has devised a method of operation as follows: A median abdominal section is made from 3 to 4 inches long and at the usual site between the umbilicus and pubis. The adhesions are broken up and the fundus brought forward. The patient is then placed in the Trendelenburg position, and the round ligament on one side seized and brought to the opening. A silk thread is carried under the ligament by means of an aneurysm needle at a distance of about 1½ inches from the uterus. The other round ligament is secured in the same way and the ends of the thread brought out of the abdomen and held in the bite of another snap-forceps. The fascia, muscle and peritoneum at the margin of the incision are then caught with a volsellum an inch or so from the lower angle of the incision, and traction is made. This pins the layer together and prevents retraction of the muscle. Specially devised perforating forceps are thrust through into the peritoneal cavity and seize the thread which holds the round ligament. The clamp forceps are removed from the latter and the perforating forceps withdrawn. This brings the thread and ligament through the perforated wound in the abdominal wall. The ligament is held taut and fastened into the wound. The opposite side is treated in the same manner and the median abdominal incision closed. [W. A. N. D.]

11.—Ramas writes upon the **variability of the tubercle bacillus**, and concludes that this bacillus is not always easy to demonstrate. The staining reagents cannot be depended upon absolutely. The bacilli from different patients, and occasionally at different times from the same patient, may react to stains in different ways. Physical and chemical changes in the bacilli probably influence the tinctorial variations. When distinct physical signs of tuberculosis exists, even in the absence of demonstrable tubercle bacilli, the diagnosis should be made so as to give the patient the benefit of the doubt, and treatment instituted promptly. [F. J. K.]

12.—Philbrick writes upon **Medical Colleges and Professional Standards**. The author states that the United States Commissioner of Education reported that in 1894 there were 23,778 medical students. The percentage increase of medical students between the years 1875 and 1899 was 177. According to the United States Commissioner of Education, in 1899 there were 151 medical colleges, and according to the Secretary of the American Medical Association there

were 173. The author contends that the medical colleges exists in excess of public demand, and that this great increase of colleges tends to lower the standard of instruction. He concludes the article with a protest that the profession should discourage the entrance of unfit medical men into the profession. [F. J. K.]

13.—Minor gives an account of **Philippine Customs and Habits**. Sanitation among the Philippines is much neglected, this being especially true in regard to the disposal of sewage and waste. The author emphasizes that during the next decade great changes will undoubtedly occur in the Philippino medical world, as well as in the management of their civil government. [F. J. K.]

14.—Spibak believes that the **work of establishing medical departments in public libraries** which has already been begun, will continue. The author contends that every public library should be supplied with books which pertain to medical questions. [F. J. K.]

13.—The patient already described in Vol. X of this Zeitschrift, gradually showed progressive involvement of the muscles until death occurred from exhaustion. The intelligence remained normal and the bladder and intestines were not involved. The autopsy showed that the ganglion cells of the anterior cornua of the cord had almost entirely disappeared; the anterior roots were very much smaller and paler than normal; the blood vessels and neuroglia tissues were normal, and there were no changes in the white substances of the cord. The degeneration was also found in the peripheral nerves; the posterior roots were entirely normal. The muscles showed marked degenerative changes. The muscle spindles were present in all the muscles in excessive numbers. The intra-muscular nerve fibres were degenerated. The autopsy therefore confirmed Hoffmann's belief that the disease was one of **progressive spinal muscular atrophy**. He also reports 2 cases, one occurring in a boy of 15 months, and the other in a girl of 2 years. They both presented atrophy of the muscles, and in the boy fibrillary twitchings had been observed. The muscles gave the typical reaction of degeneration, and the reflexes were lost. The muscles of the girl failed to show any fibrillary twitchings. The electric reactions are

14.—Dinkler in the past 4 years has observed 37 cases of **tabes dorsalis**. Thirty-one of these admitted venereal infection. Three of the others had undoubted syphilitic manifestations. The remaining 3, 2 women and one man, the latter having also signs of general paresis, failed to present any syphilitic lesions. Seventy per cent. of these patients belonged to the laboring class. In 30% there was a history of more or less excessive alcoholic indulgence, and in 20% the patients had used tobacco to excess. The other alleged causes only occurred in 1 or 2 cases each.

Dinkler calls attention to the fact that excessive indulgence in alcohol and tobacco occurs much more frequently in neurasthenics than in cases of *tabes dorsalis*. In 3 cases it was possible to obtain an autopsy and to make careful microscopic examination of the cord. The examination showed moderate alteration in the dura, pia and arachnoid. There was some increase and thickening in the fibrous tissue, loss of the endothelial cells, and in the pia some round cell infiltrations occurring in groups. In a 2d case there was atrophy of the dura, thickening of the arachnoid, and round cell infiltration of the pia, particularly around the blood vessels. The 3d case showed essentially similar conditions. The author also reports a case of **syphilitic meningitis** in which there was round cell infiltration of all 3 membranes, and an **ascending degeneration in the posterior columns**, not so very different from that discovered in locomotor ataxia. In order to determine whether these changes occurred in other forms of nervous disease Dinkler examined cases of syringomyelia, muscular dystrophy, Friedrich's disease, amyotrophic lateral sclerosis, multiple sclerosis, etc., and in none of them was there any distinct round cell infiltration or vascular alterations, with the exception of one case of multiple sclerosis and one of sarcoma of the pia. He therefore regards these changes as specific. [J. S.]

15.—Fleiner discusses **gastric tetany**. It usually occurs in patients whose nutrition has been greatly impaired, and who have an extreme gastrectasis as a result of stenosis of the pylorus or duodenum. The disease it probably less common than formerly, because gastro-enterostomy is performed earlier. When the complication does arise it usually occurs suddenly. He has already reported 4 cases, and now adds a 5th to these, which in many respects, is exceptionally interesting. The patient, a man of 51, of enormous strength, had had gall-stones and adhesions between the gall bladder and the intestines. The gall stones had also perforated into the stomach and duodenum, and as a result scars had been formed that led to severe pyloric stenosis. In spite of careful diet, rest in bed and frequent lavage the patient gradually grew worse, lost in weight, and the daily quantity of urine decreased. It was decided to perform gastro-enterostomy, but just before this was done the patient developed symptoms of complete pyloric stenosis, profuse vomiting, and upon washing the stomach, food was found that had remained in the stomach 6 or 7 weeks. The following day during lavage feces were obtained, and the patient suddenly had a severe tonic spasm of the arms and legs, which subsequently involved the body and face, and lasted several minutes. At the same time there was intense pain and paresthetic sensations which lasted for 12 days. The reflexes were lost. Trousseau's symptom was easily elicited. Examination of the stomach contents for amines was negative. The patient after this attack was so weak that it was impossible to perform an operation. He remained in a state of collapse for 12 days with a marked tendency to tonic contractions of the extremities. The blood gave symptoms of anhydremia, and death finally occurred as a result of hypostatic pneumonia, without fever. In addition to these tetanic cramps patients sometimes have simple tonic cramps without Trousseau's symptom. The attack always occurs as a result of profuse vomiting or lavage in which large quantities are obtained from the stomach. The symptoms are not very dissimilar from those of the tetanus that results from removal of the thyroid gland. An associated symptom was diminution of the reflexes and of pupillary activity. Fleiner regards the etiology of the condition as the development of tonic cramps as a result of muscular exertion and possibly as a result of the poverty of the tissues in water. [J. S.]

16.—Hoffmann reports the case of a man 52 years of age, without luetic infection, whose sickness commenced with uncertainty of gait, then left-sided hemiplegia, dilirium, hemianesthesia, disappearance of the tendon reflexes, and marked ataxia of the right leg. There was no papillitis. Death occurred 4 months after the appearance of the first symptoms. At the autopsy a **glio-sarcoma of the right hemisphere** was found that included a great portion of the centrum ovale, had compressed the right lateral ventricle and anterior portion of the internal capsule. Above this tumor the nerve fibres had degenerated, and there was a descending secondary degeneration in the pyramidal tract from the internal capsule. In the spinal cord, this degeneration gradually disappeared. In addition there was **degeneration in the posterior columns**, most pronounced in

the lumbar cord where the whole of the posterior column and Lissauer's zone were degenerated. The posterior roots showed moderate degeneration in this region. In the dorsal and cervical portions of the cord the degeneration was found near the posterior part of Goll's column. The nucleus fascculus was normal, and no ascending degeneration could be found above it. It appears from this case that a diagnosis of brain tumor and *tabes dorsalis* may be justified. The question arises whether or not the two conditions are entirely independent. As the March stain gave very slight traces of degeneration in the posterior columns, it seems reasonable to suppose that the degeneration there is older than that in the pyramidal column, where the black fibres were very numerous. This does not necessarily prove that all the degeneration in the posterior column is older, and even if it were, it might easily occur sooner as a result of the tumor, than the degeneration in the pyramidal column. Moreover, there is no history of syphilis. The disease commenced about 4 months before death. There was no disturbance of sensation on the non-paralyzed side and the patient had the Argyll-Robinson pupil. Hoffmann concludes that the case is not one of true *tabes dorsalis*. He discusses the various conditions that might give rise to degeneration in the posterior cord, among which he mentions anemias and cachexias, intracranial increase of pressure, venous congestion or thrombosis. He concludes that although we do not know the mechanism by which this is brought about, brain tumor can cause changes in the spinal cord that cannot be distinguished from posterior sclerosis. He suggests that perhaps the organic changes in one part of the central organs may produce disturbance of nutrition in all others. [J. S.]

17.—Brauer reports the case of a girl 19 years of age, who had had numerous tuberculous lesions in the body, and who finally developed kyphosis resulting in complete paraplegia with paralysis of the sphincters and loss of sensation. On the right side she had until death increase in the patellar reflex and ankle clonus. On the left side the patellar reflex was obtained with much difficulty. The left foot had been amputated. At the autopsy a tuberculous myelitis of the upper portion of the dorsal part of the spinal cord was found, causing, as was proved by microscopic examination, complete obliteration. **Complete separation of the cord** had occurred in the most affected part, the distance between the ends being not less than 4 mm. The dura was thickened and there were the typical forms of ascending and descending degeneration. The author discusses the reason why the **patellar reflex was preserved**, suggesting that perhaps there might be irritation on the right side as the result of the amputation on the left, or that the tuberculous process does cause enough irritation to stimulate the cells in the lumbar enlargement, and whether the irritation conducted along the peripheral nerves from the lesions in the ankles could be sufficient. He is unable to decide which of these hypotheses (if any) is correct. He also reports the case of a boy, 8 years of age, who fell from a tree and immediately had complete paraplegia with loss of sensation. There were evidences of fracture of the spinal column. The reflexes were absent on both sides; there was complete paralysis of the sphincters, and decubitus appeared. Two months later suspension was commenced. The muscles then showed considerable irritation, contracting when the skin was struck, and in the course of a few weeks the tendon reflexes reappeared and there was ankle clonus. An operation was performed, but no changes were found in the spinal cord or in the dura. The latter was not opened. It seems reasonable to suppose that in this case there was a complete transverse lesion of the cord on account of the absence of a tendency to recovery. Numerous experiments showed that under certain circumstances the patellar reflexes reappear some time after complete division of the cord. The author presents a number of experiments that he performed upon rabbits in which this result was obtained. He suggests that perhaps the loss of the reflex is due to the accumulation of cerebrospinal fluid in the lumbar region, and that as this is gradually absorbed they reappear. [J. S.]

18.—Strümpell and Barthelmes report the case of a man, 31 years of age, without significant previous or family history, who on awakening one morning had severe pain in the lumbar region and in the thighs. The next day these were much more severe. Two days later he had profuse perspiration and the pains ceased. The legs were then very weak and finally became completely paralyzed. When

admitted to the hospital some months afterward, it was found that the cranial nerves were normal; the spine was not tender; both legs were emaciated; there was flexion at the hips, but practically none at the knees and ankles. The quadriceps appeared to be atrophied; the sartorii were still normal; the tendon reflexes were lost in the legs; the plantar reflex was active. Sensation was not disturbed. Electrically all the muscles of the abdomen and the 2 sartorii were normal, the other muscles of the limbs, the adductors on the right, and the glutei muscles did not react to any current. The patient improved somewhat under treatment, but no essential changes occurred. The authors believe that this is a case of **acute poliomyelitis** on account of the absence of sensory symptoms, the acute onset, the pains in the back, and the character of the subsequent paralysis. They believe that the lesion involved the 4th and 5th lumbar, and the 1st sacral segments on the right side, and the 2nd, and 3rd lumbar and the 2nd sacral segments on the left side. The fact that the sartorius was not affected shows that the general belief is correct that this muscles is supplied from the lumbar segments. The cremaster reflex was also preserved, which accords with the localization given. They give a classification of the atrophic forms of paralysis, which is summarized as follows. First, acute local neuritis; second, acute local poliomyelitis; third, hematogenous toxic degeneration of the motor nerves; fourth, acute, sub-acute and chronic toxic degenerations of the peripheral motor neurons; fifth, progressive atrophy of the motor neurons, including neuritic and spinal atrophy; sixth, progressive muscular atrophy; and seventh, amyotrophic lateral sclerosis. [J. S.]

19.—Gierlich reports the case of a man, 38 years of age, who suddenly developed intense pain extending from the right hip down to the foot. Subsequently there was paralysis and atrophy of the various muscles of the right leg. Then, 8 weeks later, there were similar pains in the left hip and leg. When examined there was loss of sensation on the anterior surface of both thighs, both legs, and the external surface of both thighs and legs, and the back of both feet. There were reactions of degeneration in the muscles supplied by the cranial and obturator nerves. There were no tender points over the nerves and therefore, **degeneration of the sacral roots** seemed to be present. As the sphincters were not involved there is no reason to assume involvement of the spinal cord. The roots affected were probably those proceeding from the 2nd to the 5th lumbar segments. The nature of the lesion of course cannot be known, but it was probably tumor. Possibly the condition was syphilitic. He also reports the case of a man, 20 years of age, who received a severe injury to the lumbar vertebra, followed by intense pain in the small of the back, extending down the right leg to the back of the foot. This was followed by loss of sensation in the right leg, loss of movement in the right foot, and some wasting of the muscles. When examined 5 months later there was loss of sensation in the anterior portion of the right foot, and hypesthesia of the right thigh. It appears likely that the lesion involved the **roots extending from the 4th and 5th lumbar segments** on the right side. Gierlich discusses his case in the light of recent studies in the localization of spinal disease, criticises Wichmann's work, because no distinction is made between segmental and root lesions, and expresses his admiration of the work done by Head. He draws the following conclusion regarding spinal localization, from this case. The ilia-psoas and sartorius muscles are innervated from below the 1st lumbar, the gluteal muscles and the flexors of the knee and foot have no innervation from the 2d to the 5th lumbar segments. The dorsal flexors of the foot receive their innervation from the 5th lumbar segments, although the extensor communis dig. brevis, receives its innervation from the deeper segments. The fact that touch sense is less extensively lost than temperature and pain sense indicates that these fibres pass from a given area to the spinal cord through more than 3 dorsal roots, although it is probable that the middle root is in most direct association with the area involved. [J. S.]

20.—Bettermann reports a number of **types of skin disease occurring in hysterical patients**. He mentions particularly dermatographismus, erythemia, hemorrhages, urticaria, forms of edema, solitary and multiple ulcers, gangrene and eczema-like eruptions. He reports a number of cases illustrating various types of these conditions. Among them a girl, 19 years of age, who during her first pregnancy had severe eruptions all over her body. This was

soon localized to the right arm and breast. This was associated with an eruption limited to the same region, in the form of large, round red plaques slightly elevated, sharply limited, with some blisters and papules around their edges. There was moderate dermatographia. After delivery this eruption rapidly disappeared. The hand was not involved. The patient had numerous hysterical stigmata, and Bettermann believes that the eruption was purely hysterical in character. He also calls attention to the frequency with which hysterical patients will mutilate themselves for various reasons, and reports 2 cases, in one of which ulcers were produced by caustic potash, and the other by hypodermic injections of a mineral acid. He reports another case in which a woman during her second pregnancy had a severe eruption, papillary in character, involving the outside of the right arm, shoulder and lower portion of the face and head on the right side. She had hysterical stigmata. It is possible that there may be hysterical affections of the roots. [J. S.]

21.—Arnsperger reports a case of **locomotor ataxia** which presented typical **athetoid movements** of the fingers of both hands. These disappeared during sleep but reappeared on awaking and were increased by excitement or severe labor. There was also intermittent Argyl-Robinson pupil. He reports another case: a man, 51 years of age, who in addition to the typical symptoms of tabes dorsalis had athetoid movements of the hands and feet, and nystagmus. It was possible that the athetoid movements were due to the frequent involvement of the optic thalamus. [J. S.]

22.—Hanser in a long article upon **angioneurosis and neurangiosis** discusses the anatomy and physiology, the symptoms, prognosis, and treatment of these conditions. He concludes that the blood supply of the peripheral nerves is of such character that under pathologic conditions the functions of the nerves may be impaired. Thus, severe disturbance of circulation such as thrombosis may lead to severe degeneration. Slight disturbances may have no effect on the nervous system. Transitory disturbances may however, cause transitory disturbances in the peripheral nervous system, and give rise to the so-called angioneuroses especially in individuals with neurotic tendencies. The venous system is quite as important as the arterial system; the nerves chiefly affected are the sensory, possibly also the secretory but practically none of the trophic nerves. It is possible that intermittent claudicaria is one of the manifestations of this condition. The treatment consists in the anti-rheumatic and anti-neuralgic remedies, hypodermic, electricity and very rarely narcotics. [J. S.]

23.—A child of 7 had an attack of typhoid fever, and on the 9th day of the disease became somewhat stuporous. When the physician approached the bed she closed her eyes, blushed violently and could not be persuaded to speak. This condition continued until the 58th day, when speech suddenly reappeared. She again became mute and on the 63rd day, when for the first time she was without fever, she commenced to respond to questions by gestures. On the 67th day she was hypnotized and suggestion was made that she could speak as soon as the faradic apparatus began to sound. From this time she spoke freely. The symptoms were not those of amnesia nor motor aphasia, and therefore a diagnosis of **mutism** was made. There were no other hysterical stigmata. [J. S.]

A Case of Pneumococcic Endocarditis.—At a recent meeting of the Medical Society of the Paris Hospitals. *Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, No. 8), Launois and Paris reported a case of pneumococcic endocarditis in a man of 46, who had pneumonia and arthritis of the wrist. On the seventeenth day of his illness he grew decidedly worse, and a loud diastolic murmur appeared at the aortic area. The pulse became typical, distinctly Corrigan in character. With this there was some fever. A systolic murmur was audible over all the larger vessels. He died 10 days later, with meningitic symptoms. At the autopsy, beside the pulmonary, pleural, arthritic, and meningitic localization of the pneumococcus, the heart showed no hypertrophy, and little dilatation, but large vegetations upon the aortic valves. Microscopically they consisted of fibrin and pneumococci. The endocarditis occurred suddenly, the sphygmograms, made 23 hours apart, showing a striking difference. The pathologic lesion occurred just as it does experimentally. Pneumococci, when they invade the heart, generally attack the aortic valve. [M. O.]

Special Articles.

A NEW HEMORRHOIDAL CLAMP.

By G. MILTON LINTHICUM, A. B., M. D.,

of Baltimore, Md.

Professor of Rectal Diseases and Physiology at Maryland Medical College

Mr. Henry Smith, in speaking of the clamp and cautery operation, which he originated, says of the clamp, "that it is very essential for its right action that the blades be so constructed as to have their parallelism complete when they meet, otherwise the enclosed membrane may slip." This is the ideal which he desired to obtain in his clamp, yet fails to accomplish. For in clamps constructed like scissors, when the portion of tumor external to the blades is cut off, the tissues often slip through except that portion which is near the heel of the instrument, where the pressure is greatest, and thereby permits serious bleeding. Gantt's clamp, by having the handles join the blades at a right angle, accomplishes the parallelism, but the arrangement of joint at the ends of handles makes it imperative to use the thumb screw to obtain sufficient pressure to clamp and hold the tissues, thus requiring the use of both hands, in this way prolonging the time of the operation, and necessitating an assistant. I also find the handles to be in the way of excising the excess of tissue and of cauterizing the stump. The scissor joint is, of course, the form of leverage in which the greatest degree of pressure may be obtained, so if it is possible to get parallelism with this form of joint we get, in my judgment,

ment, an instrument which fulfills all the conditions demanded of it.

I have accomplished in my clamp parallelism with crossed joint by using a mechanical arrangement somewhat similar to Goodell's Dilators.

This arrangement is clearly shown in the accom-

panying cuts, so I will not attempt to give a description.

In this clamp the greatest pressure may be obtained, which is the same at all points of the blades by virtue of the parallel blades.

The parallel position is maintained in all the movements, at the widest separation as well as at

the closure. I feel that the conditions are all met in my clamp, viz.: great pressure, to prevent hemorrhage, and firm hold, to prevent slipping. The instrument is so constructed that it may be dis-jointed and thoroughly cleansed and sterilized A. One cut shows a front view with clamp open: besides it are the blades of another clamp open, showing a relative position of the two instruments, demonstrating how, if a fibrous mass is caught in heel of blades no pressure would be felt at the ends of the blades

B. The back view shows clamps closed, with its mechanism.

I am indebted to the Willins Surgical I. Co. for embodying my ideas in a neat, strong and compact instrument.

A Case of Acute Hemorrhagic Polymyositis.—K. N. Georgievski (*Bolnitchnaia Gazeta Botkina*, Vol. XII, No. 16) reports the case of a man 32 years old, who developed an acute fever associated with marked inflammatory hemorrhagic and extremely painful infiltrations of the skin and muscles. The lesions were transient and migratory in character, involving nearly the entire body. Tachycardia was present only during the first few days of the affection. On the 14th day of the disease the patient developed a double catarrhal pneumonia, the sputum having been found to contain pneumococci. The blood obtained from a superficial vein showed on culture the presence of a staphylococcus. The serum was also found capable of neutralizing the ferments obtained from a dead culture of staphylococcus, showing that the patient suffered primarily from a general staphylococcus infection which was responsible for the polymyositis. The patient recovered. [A. R.]

A NEEDLE FOR SILVER WIRE.

By L. J. Y. GEMELLA, M. D., B. L.,

of New Orleans.

Fig. 1 represents the needle threaded with the silver wire. The wire is passed through the cap

B (fig. 2) pinched with an artery forceps, as shown in fig. 3. The cap is then screwed on the needle (C). The needle can be made in any model. The

figures represent a model of the Hagedorn needle, McDermott & Co., of New Orleans, makers. The advantages offered by this needle are cheapness, no

traumatism of tissue in passing, and it can be threaded at home, put in a test tube and carried in an obstetric bag to be used as an emergency needle for perineal work.

2. The Figured Elements of Colostrum and Milk. RA-
CHEL R. LOURIE.

3. Rheumatic Endocarditis with Patent Ductus Botalli. JEAN HALLE and P. ARMAND-DELILLE.
4. Two Cases of Infantile Hysteria. JULES COMBY.

1.—Spillman has studied rickets in a great number of animals. It follows the same course in animals that it runs in man. It begins with indigestion, emaciation, distended abdomen, delayed dentition, etc. Then follow the bony deformities, rosary, open fontanelle, etc. These were found histologically in ducks, chickens, etc. While rickets is rare among animals, the lesions found there and those formed in infants are identical. Bad hygiene appears to be the main cause. Out of 10 animals in which Spillman attempted to produce rickets by defective feeding and bad hygienic surroundings, digestive symptoms, emaciation, etc., appeared in every case, yet not one showed any bony changes. Experiments thus confirmed clinical experience, that defective alimentation and prolonged indigestion can cause arrest of development and cachexia without rickets. Therefore the nutritive theory is not correct; nor is the chemical theory, for the deficit of lime salts is the result, not the cause of rickets. There remain the toxic and microbic theories. Spillman made more experiments with the colon bacillus. While symptoms followed, there was never any bony change. Inoculation to show a specific microbe or intoxication were without result. Yet it is possible that our methods are hardly yet perfect enough to find the specific microbe of rickets, if it exists. After reviewing the lesions found in man, Spillman concludes that rickets must be a specific intoxication from the digestive tract, causing widespread ostitis. [M. O.]

2.—Donné first discovered the figured elements of colostrum. They are nucleated colostrum corpuscles, and appear during pregnancy, lasting to the fifth or sixth day after confinement. Then the protoplasm disappears, and the crescent-shaped nucleus is freed. Leukocytes are also present, few until labor occurs, and they disappear a few days afterward. When milk is examined, the crescent-shaped bodies are seen next to fat droplets. These colostrum bodies absorb red corpuscles and stains. Lourie supposes them to be polynuclear leukocytes, transformed. They resist boiling and are not seen in cow's milk. They probably contain the soluble ferments. [M. O.]

3.—Hallé and Delille report a case of rheumatic endocarditis in a boy of 3. His mother noticed that his heart-beat was always rapid and strong. Articular rheumatism had existed a week before he was admitted to the hospital. Marfan made the diagnosis of a recent endocarditis with a congenital lesion. The apex was in the fifth interspace, 2 cm. outside the edge of the sternum, the dullness reaching the right border of the sternum. At the apex was a loud systolic murmur, transmitted to the axilla. Twelve days later, the child had an attack of pulmonary congestion, with dyspnea and cyanosis, and died. The autopsy revealed a patulous ductus Botalli and a mitral vegetative endocarditis. The congenital lesion had existed without symptoms until the organic trouble occurred. When organic heart disease is found in an infant, a congenital condition must be suspected as the predisposing cause. [M. O.]

4.—Comby reports two cases of hysteria in children. The first was a girl of 10, whose father was a drunkard, whose mother was very nervous and had hepatic colic. One child was an idiot. This one had always been emotional, and had an attack of angioneurotic edema. For over a month she had been in bed, unable to walk, with hysterical convulsions. Examination revealed nothing abnormal. In bed she could make any movement asked. But when stood up, she trembled and fell, like a paraplegic. This became worse when she tried to walk. But she could move well upon her knees. Comby considers it a typical case of hysteria, pure astasia-abasia. Three days treatment with baths, isolation and electricity cured the condition. The other patient was a girl of twelve, whose father was both nervous and alcoholic. After typhoid fever at 6 years, she had complete left hemiplegia, which suddenly cleared up after having lasted two months. Two years later this recurred and lasted three months. At 10 years, right brachial monoplegia appeared, disappearing suddenly six months later. Now she again has right monoplegia, her fourth paralytic attack. With isolation, and by the use of the... [M. FURTHER NOTES OF A CASE OF PERNICIOUS ANEMIA REPORTED AT THE MEETING OF THE ASSOCIATION OF AMERICAN PHYSICIANS IN 1900; WITH REMARKS ON THE DIAGNOSIS OF THE DISEASE.

By FREDERICK P. HENRY, M. D.,

of Philadelphia.

Professor of the Principles and Practice of Medicine, Woman's Medical College of Pennsylvania; Physician to the Philadelphia Hospital, etc.

At a meeting of the association in 1900, I reported five cases of pernicious anemia, each of which possessed features of unusual clinical interest, and made some remarks upon the diagnosis of the disease and the characteristic alterations of the blood which it presents. Exception was taken to one of my cases (case IV.)* on the ground that nucleated red cells, and especially megaloblasts, had never been found in the blood of the patient. In reply to my question as to how my critic would classify such a case as I reported, he said that he "should regard it as a case of secondary anemia of unknown origin".** He also stated that he had "had a number of such cases ending in recovery,"*** but saw no reason to regard them as cases of pernicious anemia. I will not stop to discuss the question whether, with our present knowledge, pernicious anemia may not be defined as a "secondary anemia of unknown origin," but will again refer to the implication that such cases as my case IV, are by no means rare.

I will now briefly relate the main clinical features of the case whose progress I am reporting. In vol. XV. of the Transactions, its caption is as follows: Case IV. Under observation six years, during which there have been several slight and two severe relapses, chronic gastro-intestinal catarrh, with marked exacerbations preceding and during the relapses; complete restoration to health. In the extreme reduction of the red cells (to 1,237,500 per cubic mm., i. e., to about 25 per cent. of the normal), the increased percentage (30) of hemaglobin, the hypoleucocytosis, and poikilocytosis, as well as in the symptoms both positive and negative, the case was a typical one of pernicious anemia. At the time of my report last year the patient considered himself in the best of health, and his general appearance was "indicative of vigor and activity." The recent history of the case is as follows:

I was asked to see the patient in consultation with Dr. L. D. Judd on March 29th, 1901, and found him in a state of profound anemia. I found that he had been progressively failing in strength, in other words, becoming more and more anemic, during the autumn of 1900, and that in December he had had another attack of erysipelas. A week before I saw him he had returned from a visit to Atlantic City, where he had been under the care of Dr. Philip Marvel, who, on February 27th, had examined his blood with the following result: Number of red cells per cubic mm., 1,240,000; Hemoglobin, 32%; white cells, 3,000 per cubic mm.; marked poikilocytosis. A differential count was not made, nor is anything said in the report concerning nucleated red cells. These figures are almost precisely identical with those of a count I made on February 3rd, 1894.

On one of my visits in March of the present year I made several cover-glass preparations and sent them to Dr. L. N. Boston, who reported the presence both of normoblasts and megaloblasts. Under the use of arsenic and iron the patient is steadily improving, although his urine contains a considerable quantity of albumen. This albuminuria was a feature also of the last relapse, but disappeared *pari passu* with improvement in health and strength.

I presume that no member of the association has now any doubt that this is a typical case of pernicious anemia, although, in my opinion, there never should have been the slightest question concerning the diagnosis. The demonstration of megaloblasts in the blood was not at all necessary to confirm it. There is a tendency at the present time to regard the presence of these cells in the blood as the sole criterion of pernicious anemia. According to this view, a case may present symptoms and signs and blood changes such as are not found united in any disease, except pernicious anemia, and yet, if megaloblasts are not detected in the blood, the diagnosis of pernicious anemia is unwarranted. Such a doctrine appears to me as pernicious as the disease to which it is applied, and for the following reasons: First, because, as already stated, the symptoms and signs, both positive and negative, and the blood changes of pernicious anemia, apart from the presence of nucleated cells, distinguish it sharply from all other diseases. Secondly, because nucleated cells, whether large or small, are not pathognomonic of pernicious anemia. A symptom or sign to be pathognomonic must fulfil one of the requirements of a specific germ: i. e., it must occur in association with but one disease. Now this is not the case with the cells called megaloblasts, which are found in leukemia, in bothrioccephalus-anemia, and occasionally, though very rarely, in cases of carcinoma ventriculi and syphilis.* If the presence of megaloblasts in the blood were pathognomonic of pernicious anemia, the diagnosis of that disease could be made more accurately in the laboratory than at the bedside. Now this is by no means the case, for it is impossible for the histologist to distinguish a specimen of blood from a case of bothrioccephalus-anemia from one derived from a case of that mysterious disease so well styled by Birch Hirschfeld as cryptogenetic anemia.

The diagnosis of pernicious anemia is most firmly based upon the tout ensemble of signs and symptoms, both positive and negative. The presence of megaloblasts is confirmatory of, but not indispensable to, the diagnosis. They possess a prognostic rather than a diagnostic value, for they often appear in the blood in large numbers shortly before death, and often are absent for months during periods of remission.**

With reference to the statement*** that cases of anemia with a hemic unit of 25 and a hemoglobin percentage of 30 are not rare (they cannot be rare if any individual has seen "a number" of them), and that they often end in recovery, I can only say that in a continuous service in large hospitals dating from 1874, during which time I have been on the alert for cases of pernicious anemia and conditions resembling it, I have had no such experience.

ACASE OF SEVERE ANEMIA WITH CHANGES IN THE SPINAL CORD.

By WM. E. HUGHES, M. D., and WM. G. SPILLER, M. D.,

Clinical Report by Dr. Hughes.

Daniel C., white, aet. 63 years, a native of Ireland, was admitted to the Philadelphia Hospital, Dec. 30th, 1899, his chief complaint being shortness of breath and swelling of feet and legs. There was nothing in his family history of any moment. His parents both died of old age. Three brothers died of wounds received while in the army. He had the usual diseases of childhood. Then he was well until five years ago, when he had a slight sunstroke, the especial symptoms connected with which he did not remember when questioned. The attack was not deemed of any moment at the time of its occurrence, and he recovered from it perfectly, remaining well until his present illness commenced. In July, 1899, he noticed that on running, or even walking fast, he would become suddenly short of breath and would have to stop, or even sit down, till he had recovered himself. This became steadily worse until any effort distinctly inconvenienced him. Three weeks before admission his feet and legs began to swell toward evening. At first the swelling would disappear by morning, but by the time of his admission it had become persistent, though worse toward night. During most of his illness he complained of feeling cold and chilly. Throughout this time, too, his bowels were rather loose, though not persistently so. There had been no hemorrhages. On admission his skin was dry and glazed and of a peculiar, uniform waxy pallor. There was some puffiness of his eyelids and edema of his face. The feet and legs were edematous

condition. The urine had a specific gravity of 1016, was acid in reaction and contained neither sugar nor albumin. He had not lost much flesh. The digestion had been good. Jan. 4th, 1900, a blood examination gave 780,000 red corpuscles and a hemoglobin value of 20%. The next day another examination gave 671,518 red corpuscles, 3,000 white corpuscles, hemoglobin 18%. A majority of the red cells were larger than normal, but there were great variations in size and outline. Normoblasts and megaloblasts were present in numbers. Jan. 7th, reds 760,000, whites 2,400, hemoglobin 20%. Gastric disturbances had developed and he had come to vomit nearly everything ingested. He gradually grew worse, his dyspnea amounted to orthopnea, and he died of exhaustion Jan. 16th. The temperature ran about normal, the highest being 99.8.

Autopsy. The pericardial sac contains 30 c.c. of straw colored fluid, in which float numerous threads of fibrin. On the anterior surface of the right ventricle is a large white patch of fibrous thickening. All the cavities of the heart contain dark fluid blood and a few currant jelly clots. The valves of the right heart are normal. The mitral orifice is of normal size; on parts of the free margin of both leaflets is a slight thickening. The aortic valve is normal. The heart muscle is dark reddish brown in color. In the papillary muscles of the left heart is a distinct yellow mottling showing through the endocardium. The wall of the left ventricle is 14 m.m. thick, the right 9. The coronary arteries are slightly thickened but their lumen is little encroached upon.

The pleural cavities contain 110 and 250 c.c. of clear straw colored fluid respectively. The lungs are voluminous, their anterior edges nearly covering the pericardium and almost meeting. On their free edges dilated vesicles are plainly seen. The lung substance is light pink with considerable pigmentation, and exudes from its cut surface large quanti-

Fig. 1. Dense fibrous adhesions between the lungs and the pericardium.

Pulse was slow and full, but had very low tension. The heart was slightly enlarged, the apex beat could scarcely be felt and there was a systolic apex murmur, transmitted into the axilla. The right lung expanded poorly, there was some dullness at the base posteriorly with distant weak breath sounds and some crackling rales. The left lung was negative. The sight in the right eye was nearly gone, the result of an accident, while in the left it was normal and this pupil reacted well to light and distance. He could scarcely walk on account of physical weakness but his station seemed to be fair. The reflexes were present but were sluggish, which was thought to be due to his physical weakness. There were no electrical reactions taken. Sensation seemed to be preserved but this could not be absolutely determined on account of his low mental

ties of frothy mucus. At the apex of the right lung are numerous depressed scars, some of them extending deep into the substance. The bronchial mucous membrane is covered with considerable mucous exudate. The bronchial lymph glands are considerably enlarged and deeply pigmented.

Spleen is of moderate size. Its capsule is thin and light colored. Its parenchyma is soft, pulpy and easily scraped. The adrenals are normal in size and show no pathological condition. The kidneys are of moderate size. The capsule is slightly adherent in places and leaves a slightly uneven surface. The cut surface is pale, the pyramids of a grayish white color. The cortex measures 7 m.m. The pancreas shows no pathological change. The liver is of normal size and of light reddish brown color. In the region of the gall bladder are numerous adhesions between gall bladder,

liver and intestines. The wall of the gall bladder is not thickened and it contains no stones. The cut surface of the liver is light reddish brown in color, mottled with yellow, points corresponding apparently with the centers of the lobules.

The mucous membrane of the colon is thickened but otherwise normal. That of the small intestine and stomach is healthy. The appendix is only a short stump, the lumen of which is closed by scar tissue. The mesenteric lymph glands are dark brown in color and of a moderate size. The cerebro-spinal fluid is increased in amount.

PATHOLOGICAL REPORT BY DR. SPILLER,

From the Wm. Pepper Clinical Laboratory (Phoebe A. Hearst Foundation).

The sclerosis in the spinal cord is most pronounced in the upper thoracic and cervical regions and is more intense in the left lateral column than in the right lateral column in these regions. It is diffuse in these portions of the cord, i. e., it is not confined to any distinct system of fibers. In the posterior columns the degeneration is most noticeable in the ventral portion. The anterior columns are more nearly normal than the other portions of the white matter of the cord, but the neuroglia is proliferated somewhat here also. The anterior and posterior roots appear to be normal. The crossed pyramidal tracts are degenerated as far as the sacral region, and the left is more degenerated than the right, because the diffuse degeneration high in the cord is more extensive in the left lateral column. The degeneration below the midthoracic region is systemic in the lateral columns, i. e., it is confined to the crossed pyramidal tracts. In the lumbar re-

Fig. 1. The vessel external to the cord near the posterior end of one side. The walls of this vessel are much thickened.

gion the Marchi method reveals no recent degeneration. No swollen axons are found. The nerve cell bodies of the cervical and lumbar regions stained by thionin are not distinctly abnormal, but some of them are intensely pigmented. The blood vessels, both the intramedullary and the extramedullary, have much thickened walls, and the small intramedullary vessels are thickened not only where the sclerosis is dense, but also where the tissue of the cord is normal. The walls of many of the vessels have a hyaline appearance, and the thickening im-

Fig. 2. Degeneration of the right anterior pyramid.

gion the posterior columns are very slightly sclerotic. In the medulla oblongata the right anterior pyramid is much degenerated, but the left anterior pyramid appears to be normal. The degeneration is traced above the motor decussation as high as the mid-portion of the pons on the right side, but whether it extended much higher or not I cannot say, as the cerebrum was not in my possession. The right pyramidal tract above the decussation is, therefore, degenerated, while the left is intact; but the left crossed pyramidal tract in the cord is more degenerated than the right, where the alteration is distinctly systemic, i. e., in the lower portions of the cord. A section from the cervical region stained by

plicates all the coats of the vessels. No round cell infiltration or hemorrhage is found in the spinal cord, or spinal pia. The only sign of a hemorrhage I have been able to detect is an accumulation of blood pigment about a small vessel in the motor tract in the left side of the pons.

The literature on diffuse degeneration of the spinal cord in cases of severe anemia has become extensive. Cases in this city have been reported by Burr and Lloyd, and we have recently had in the paper by Putnam and Taylor a careful presentation of this subject.* Credit must be given to Putnam

*At their session of the 15th of January, 1900, the American Medical Association met in the Hotel Hamilton, New York City, and the following resolutions were adopted: Resolved, That the American Medical Association, in the

Fig. 1. A structure near the posterior root of the spinal cord which appears to be a thickened blood-vessel containing a blood clot.

and Dana for first showing that alteration of the spinal cord, similar to that occurring in pernicious anemia, may result from malnutrition, even when intense anemia is not present. Paresthesia, ataxia, etc., may in these cases persist many years with little alteration of the spinal cord, and, on the other hand, the intensity of the alteration in the cord may be much greater than the clinical signs would lead us to expect, and in some cases pathological conditions of the cord have existed without clinical signs. The few symptoms, feebleness of gait and diminished knee jerks, indicative of implication of the nervous system in Dr. Hughes' case, is not unlike what has been observed in some other cases, and sensation could not be determined on account of the patient's mental condition, but the intensity of the alteration in the spinal cord suggests that paresthesia may have existed. In case 2, for example, of Taylor's part of the recent paper by Putnam and himself, the patient is said to have had some numbness of the arm occasionally, and of the lower limbs, and tremor of the upper limbs, but no other nervous symptoms are mentioned, and yet the alteration of the spinal cord was intense. This case is not alone in the literature. As in many reported instances, the alteration in Dr. Hughes' case was more marked in the cervical and upper thoracic regions than in the lower thoracic and lumbar portions of the cord, and the degeneration was diffuse in the former portions, i. e., it was not confined to definite tracts, and systemic degeneration was present only as a result of diffuse lesions. Descending degeneration in the crossed pyramidal tracts has occurred as a result of injury of the fibers of these tracts at different levels of the cord, but the degeneration in the lateral columns in the cervical region extended beyond the area of the motor tracts, and in the posterior columns did not invade the root entrance zones. The anterior and posterior roots were not degenerated. So far the findings are not unlike those of Putnam and Taylor and some other investigators, but the condition of the blood vessels makes the case unlike any of the five studied microscopically by Taylor. In only two of his cases was there any alteration of the spinal vessels, and in those it was slight. In one case many of the vessels within the cord had moderately thickened walls and were in a condition of hyaline degeneration. The pia and its contained vessels were normal. In another case a slight hyaline thickening of the walls of the smaller vessels was observed in the degenerated areas, but there was

no general arteriosclerosis. Taylor considers the vascular changes he found of very little importance. The alteration of the blood vessels in diffuse degeneration of the spinal cord has varied in the different cases studied. Minnich found diseased blood vessels in the cord, and Nonne, in a recent paper, says he found the vessels unaltered when the cord tissue was unaltered or only slightly degenerated; but in the advanced cases the vascular changes were pronounced, and the relation of foci of degeneration to altered vessels was striking. In advanced cases Nonne never failed to find vascular alteration. He believes that some hypothetical poison causes the anemia and degeneration of the spinal cord, and is conveyed by the blood vessels of the cord, and that after a long contact of this poison with the vessel walls alteration of the vessels is produced, and this alteration of the vessels contributes to the formation of a vicious circle. He has even observed thrombosis, followed by softening, and Dana also, in a case of diffuse degeneration of the cord, has reported softening of the cord, presumably from thrombosis of the artery of the anterior fissure. Jacob and Moxter found in all their cases of anemia multiple foci of degeneration in the cord about the vessels and septa. They found alteration of the vessels in normal as well as sclerotic portions of the cord, and observed thickening of the adventitia and of the glia surrounding the vessels. The vessels in some of the foci were unaltered. They, therefore, conclude that the changes in the walls of the vessels were not the cause of the degeneration of the white matter of the cord, but they believe that the process almost constantly begins in the formation of perivascular and periseptal foci of sclerosis. The vessels of the cord, in the cases examined by Russell, Batten and Collier, in the affected areas were engorged and their walls thickened, but there was no actual thrombosis. In the unaffected areas the vessels were neither engorged nor thickened. In one of their cases the middle coat of the vessels appeared to have undergone a hyaline change. Hemorrhages within the white and gray matter are a common finding in pernicious anemia, according to Jacob and Moxter, and some investigators have regarded the hemorrhages within the spinal cord as a partial cause of the degeneration of the white matter, while others have looked upon them as unimportant. They were entirely absent in the cord in Dr. Hughes' case, and only in one place in the pons was any indication of a former hemorrhage found. What is the meaning of the conflicting statements regarding the condition of the blood vessels in diffuse degeneration as made by different investigators? In Dr. Hughes' case the vascular alteration was exceedingly pronounced; in a case of diffuse sclerosis reported by Dr. J. Hendrie Lloyd, microscopical sections from which I have studied in order to determine the condition of the vessels, the latter were not diseased, and in an unpublished case of Dr. Dermum, I have failed to find much alteration of the vessels outside of the sclerotic areas. It must be, therefore, that vascular changes may aid in the development of sclerotic tissue, but degeneration of the nervous tissue may begin before any thickening of the walls of the vessels is detected, and it seems not improbable that some toxic substance in the cir-

ataxia of the arms and legs; knee jerks were absent, and that the pupils were Argyll-Robertson in type.

A note was made by the resident physician in the nervous wards on May 8, 1899, which seems partly contradictory to the above statement, unless it indicates that the knee jerks were brought out by reinforcement. The note was as follows: "Knee jerks present and reinforcing; tremor of the left hand on motion; station fairly good, little sway; ataxia of arms; gait slow but not characteristic" (this probably meaning not characteristic of tabes dorsalis). It was also noted that the pupils were myotic, did not respond to light, but responded in accommodation and convergence. The patient complained at this time of headache and pains in his joints.

On September 20, 1899, the following ward notes were made; the patient complains only seldom, and then of only slight pains in the joints. His tongue is protruded straight with slight tremor. Extraocular movements are good, but he has Argyll-Robertson pupils. He can read small print. Station is fairly good, but there is slight swaying which is more marked with the eyes closed; arm movements are slightly ataxic.

The tendon and muscle phenomena were as follows, being practically the same for both sides. Knee jerks absent; quadriceps jerk absent; tendo-Achillis jerk slight; gastrocnemius jerk present; patellar clonus absent; ankle clonus absent; biceps jerk present; triceps jerk present. Plantar reflexes were present, and cremasteric jerks absent. Tactile, pain and temperature sense seemed slightly impaired in the lower extremities, the sensory response being prompt elsewhere. About the same date (September 20, 1899), an ophthalmoscopic examination was made, of which the following is a record. **Right eye:** The pupil is dilated one-third and evenly; incipient optic nerve degeneration is present; the deeper layer of the nerve head is very gray, especially at the temporal half; retinal veins are somewhat small; a few senile degenerative areas are seen in the retina and mark off old retinal extravasations; a fresh and deeply seated hemorrhage of the papillo-macula region is present and extends well out into the macula region itself. There are small isolated areas of fatty degeneration and hemorrhage, especially down and out from the disc. The vessels show a low grade of endarteritis. **Left eye:** The pupil is 1.5 mm. in diameter, immobile to light, but prompt in accommodation and convergence.

October 22, 1899, six days before his death, it was noted that the knee jerks and tendo-Achillis jerks were absent; that the Babinski reflex was present on both sides, and that the response to touch and pricks was felt in the feet and legs, although no accurate determination could be made. The man died October 28, 1899.

NECROPSY NOTES.

The body of an aged male, emaciated, showing considerable greenish discoloration of the abdomen, marked suggestion over the posterior aspect of the body with small petechial hemorrhages. Rigor mortis is not marked. Subcutaneous fat is scanty; the muscles are pale.

The left pleura shows adhesions at the apex and base, and is dissected loose with difficulty; the right pleura is likewise universally adherent, and dissected loose with difficulty, the pulmonary tissue being torn in trying to loosen the pleura.

The left lung is intensely pigmented. The surface of the lower lobe shows numerous lobules varying in size from a few mm. to 5 cm. The apex contains a large number of small greyish nodules, the largest of which are not over 25 cm. in diameter. Many are calcareous, and in a few places small masses of lung tissue are found which do not float in water.

The pericardium contains two drachms of straw colored fluid, and is apparently normal.

The right auricle is distended with postmortem clots; the right ventricle contains several chicken-fat clots, which extend into the pulmonary arteries. The left auricle is also distended and contains postmortem clots. The valves of the right side are normal. The auricular-ventricular opening admits three fingers, the mitral two fingers. The aortic leaflets show considerable thickening at the free margins, and on ventricular margins the aortic cusps are slightly thickened. The coronary arteries are slightly rigid, but not markedly atheromatous. The left ventricular wall is thicker than the right, the left being 4 cm. and the right 2.8 cm. in thickness. The myocardium is slightly pale, but is dense and firm.

The splenic trabeculae seem a little more prominent than usual, and the organ somewhat denser, otherwise it is normal. The left suprarenal is apparently normal. The left kidney shows some diminution of the cortex, and contains cysts. The capsule is extremely adherent. The surface is granular and there is some fat in the pelvis. The right kidney shows the same changes as the left. The ureters are normal. The bladder is slightly ribbed and there is faint enlargement of the middle lobe of the prostate, not very marked. The glandular structure of the pancreas is normal. The liver is cirrhotic. The biliary ducts are normal.

The lumbar nerves were dissected out continuous with the cord. The brain and the cord were left in continuity, except a small segment.

Patient died 4.45 P. M., October 28, 1899. Autopsy 3.45 P. M., October 29, 1899. Path. diagnosis; chronic tuberculosis and interstitial nephritis.

THE TEACHING OF CHEMICAL PATHOLOGY.

By ALONZO ENGLEBERT TAYLOR,

of San Francisco.

Professor of Pathology, University of California.

In a recent article in this journal upon the Teaching of Pathology, Adami wrote: "Pathological chemistry gives so much promise of throwing, in the very near future, so much light upon pathology in general, that the time has come for greater activity in the teaching of this branch in immediate connection with the pathological department." The University of California has established such a course in chemical pathology, the details of which may be of general interest, particularly since in the series of articles in the journal devoted to the teaching of the various branches of medical science, there was no especial consideration of this subject.

The laboratory in which this course is being given was installed and equipped during the past year. It contains desk space for fifty students, the space allotted to each student being nearly twenty square feet. Each student has an individual desk and locker, each desk containing a sink ten by twelve inches, and is fitted with four shelves for the reagent bottles. Fitted to each desk are three water spigots, one large valve being for the ordinary supply, and two small cocks for the supply of water-baths, etc. The gas supply for each desk consists of two taps. Each desk has a vacuum pipe exhausted by a large vacuum pump. There are six hoods in the room. One is devoted to the generators of hydrogen and carbon dioxide. A second is occupied by the blast, the compressed air for which is furnished from a tank filled by an automatic air-pump. Two of the hoods contain each a copper water-bath five feet long, two feet wide and eight inches deep; these baths are heated either by live steam or by gas, and contain together 50 openings, one for each student. One hood is devoted to the Kjeldahl digestion apparatus. The remaining hood contains the hydrogen disulphide generator. There are further two large counters for distillations, etc. Each student is sup-

plied with sixty reagent bottles, a test-tube stand with twenty test-tubes, test-tube holder and cleaner, one portable water bath, two gas burners, two tripods, two stands with rings, one burette holder with two burettes, one wash bottle, two Erlenmeyer flasks, one distillation flask, one vacuum filtration flask, twelve beakers, three funnels, two porcelain dishes, one separating funnel, two weighing bottles, one pylonometer, one distillation apparatus, one saphlet extractor, one dessicator, one fractional distillation flask, one crucible, crucible tongs, one mortar and pestle, two pipettes, two measuring cylinders, one thermometer, one acrometer, and the watch glasses, pinch-cocks, files, glass rods, glass tubing, rubber tubing and filter paper required in the work. Each student has upon his desk the reagents needed in work of this character, some sixty in number. Upon side shelves are stock bottles of accessory reagents and solutions for titrations. In an adjoining room are ten saxtorius balances, dessicators, spectroscopes and polariscopes. Three afternoon sessions per week are given throughout the academic year.

The instruction is determined by the principle that the student should learn to consider disturbed function as coequal with and correlated to altered structure. Morbid anatomy and morbid physiology are considered and taught together. Such a course will contain a great deal of what is in continental writings called general or experimental pathology. The courses in chemical and morphological pathology are given to the same class, so that the two points of view are constantly correlated in the mind of the student. Chemistry, so far as its technical aspects are concerned, bears to the one course the same relation which microscopy bears to the other, that of handmaid. It is not pathological histology; it is histological or morphological pathology; it is not pathological chemistry, it is chemical pathology—the pathology is the point of view. That considerations of chemistry, physics, physiology and zoology enter into the study and teaching of pathology is, of course, a truism; but for the student of pathology and for the teacher in his duties as a teacher of pathology, it is chemistry, physics, physiology and zoology to the end and for the sake of pathology.

There are in the instruction three directions which are followed: 1. The consideration of the relations of the disturbed function to the lesions. That in many instances we are not able to define such relations is all the more reason for attempting to fix them in all cases. 2. The determination of the relations between the particular functional disturbance and the general metabolism, perhaps the most valuable aspect of the subject. 3. The training in the diagnostic procedures employed in the study of the chemism of disease, and instruction as to their real worth.

The course consists of laboratory work supplemented by such lectures as are necessary for the elucidation of the subjects in hand. So far as possible the laboratory work is individual and practical for each student. The insufficiency of material in certain diseases, however, will sometimes preclude individual exercises, and under these circumstances demonstrations (not descriptions) replace them. The course includes work upon the saliva,

the gastric secretions and contents, the fæces, the urine, the blood, exudates and transudates, the bones, various organs, tumors, ptomains, toxins, antitoxins, and ferments. It is planned to have the entire class do a certain amount of work in all the general lines, following which, individual subjects for original work will be assigned to each student, which subjects are to be worked out in detail. As illustrations may be cited as subjects: the fats of the stools of persons with pancreatic or hepatic disease; the stools of diarrheas; the urinary protein in the different forms of albuminuria; the freezing point and electrolytic resistance of nephritic urine; the amyloid substance; the fat and protein in the kidney in nephritis; the mineral constituents of atheromatous blood-vessels; the protein, fat and glycogen in pus; the composition of the fluids in ascites and edema; the organic and inorganic constituents of the bones in rachitis and in other bone diseases; abnormal urinary pigments; the protein and carbohydrates in the fluid of parovarian cysts; the dried residue of the blood and plasma, and the protein of the plasma in anemias; the purin bodies in the urine in such conditions as leukemia; the glycogen in diabetic tissues or in tumors; chyluria; the solvent action of the serum of immunized animals; the Calmette antivevne demonstration, etc., etc. These original tasks constitute a most valuable part of the work, since here the frame of mind and the scientific method are cultivated.

For the successful completion of such a course there are two prerequisites: the student must be adequately trained in physiological chemistry; and material must be abundant. A certain amount of material may obviously be prepared directly for the course. It will never be possible to take each student over the whole field, just as it is not possible to give each student work in all the lines of physiology or to demonstrate all the lesions of morbid anatomy. Nor is that necessary. If each student *works* through and *thinks* through a few of the conditions of disease, the mental training and the grasp upon the subject thus attained will be of high value, above and beyond the training in diagnosis. And for the later development of the student's medical mind, the chief object of the course is to teach the student to view disease as much from the functional as from the anatomical point of view, to correlate in the mind morbid physiology with morbid anatomy, and to carry this association into practice and into original work.

Pulmonary Sclerosis, Probably Syphilitic.—Raymond Bernard reports a very interesting case of pulmonary sclerosis found in a young man admitted to the hospital with interstitial keratitis. It was impossible to obtain any syphilitic family history. Examination, however, revealed marked thoracic deformity with scoliosis, adherent pleura, and retraction of the left lung. Exploratory puncture was negative. Over the entire left side there were no respiratory movements, but intense pseudo-cavernous breathing was heard. The sclerosis had advanced so far that the heart was drawn upward and further to the left side. Subjective symptoms were present, and when the patient was dressed, the condition was not even suspected. He had never had an acute pulmonary disease, nor was there any suggestion of tuberculosis. Yet the presence of a double intestinal keratitis decided Bernard in making the diagnosis of pulmonary sclerosis, probably due to hereditary syphilis. (*Gazette des Hôpitaux*, 1901, No. 18.) [M. O.]

THEORETICAL AND PRACTICAL CONSIDERATIONS ON THE TREATMENT OF JACKSONIAN EPILEPSY BY OPERATION: WITH THE REPORT OF FIVE CASES.

By JAMES JACKSON PUTNAM, M. D.,

Professor of Neurology, Harvard Medical School.

[Conclusion.]

To return now to the consideration of the questions specified at the beginning of the paper, it may be stated as a fact which would probably be generally admitted, that operations for the relief of focal epilepsy, whether these aim at the removal of local sources of irritation or of diseased areas involving the cortex, or of the removal of the apparently normal cortex, are often unquestionably of great benefit; although they have not accomplished nearly all that was hoped of them. Not to speak of special cases and groups of cases, some of the best of which have been contributed by American physicians, this statement is substantiated by several recent and careful compilations of German surgeons, as Braun,¹ Graf,² and Matthiolus.³

When it comes to the important question of the comparative merit of cortical excision, as against operations of less magnitude, such as simple exposure of the cortex or loosening of dural adhesions and the like, which sometimes have an extraordinarily favorable effect, the case is not so clear, especially when it is remembered that the excision is likely to cause lasting incoordination of slight degree, and that the resulting cicatrices may be by no means indifferent for the health of the surrounding parts (1) of the brain.

Still, the figures cited by Matthiolus, taken for what they are worth, indicate rather better results from operations in which the brain has been included in the operation than where only lesions of the brain coverings have been treated.

"Cures," i. e., for example, a cessation of fits for five years have been very few in number, and although such a case as that of Collins and Gerster's, is encouraging, where six years have elapsed during which, after cortical excision but under continual bromide-treatment, no fits have occurred, is very impressive, it is to be remembered that in the first case of the series reported by McCosh an equally good result followed simple trephining, separation of the adherent dura from the roughened bone, and the removal of bone-fragments, although there can be little doubt that the broken adhesions instantly reformed, so that the local conditions of nutrition probably remained in the end unimproved.

The conclusions which seem to me most reasonable on the other points are the following:

Epilepsy of the "Jacksonian" type is usually set up, in the first instance, by gross sources of irritation, either peripheral or central, but for the most part

external to the brain tissue itself. Yet there is probably one form which has the same pathology with so-called idiopathic epilepsy of more common types.¹ The anatomical changes found under these circumstances are to be regarded as usually either secondary to the convulsions or else as indications of an abnormally developed brain. Perhaps uremic and other toxic convulsions of focalized type should be classified with this group, inasmuch as the poison is distributed through the brain as a whole, and the localized effect is not to be sought in the localized cause.

It is doubtless true,—as Sachs² and Collins³ have pointed out,—that in some cases of Jacksonian epilepsy degenerative changes may be found in excised pieces of the cortex, which were not recognizable to the naked eye. On the other hand, however, the evidence that these changes are of a kind likely to excite epileptic seizures seems to me insufficient, and it is especially improbable that lesions of such a character would be limited to a small area of the cortex to such a degree as to be entirely removable by operation.

Not only is the existence of such changes in the form of circumscribed focal lesions improbable, but if they existed we have no clinical criteria by which to delimit them before death. To take, for example, the most common type of Jacksonian epilepsy, that which begins with sharply defined hand-symptoms, there are large numbers of cases to show that the lesion, when gross, may be of great, or indefinite size, and may vary greatly in position with relation to the so-called hand-area of the cortex. If then a large tumor or cyst or a patch of diffuse meningitis may cause sharply localized symptoms, why should not the same be true, a fortiori, where the lesion is a diffuse degeneration of ganglion cells?

Again, it is by no means certain that in the fit of the Jacksonian type, the morbid cycle of which the convulsion is the most obvious feature, always begins with a "discharge" at the point corresponding to the signal symptom. If we bear in mind the analogous case of a purposive movement, as when, for example, we put out the hand to grasp some object or clinch the fist in obedience to some emotional impulse, we must admit that these movements are preceded by a series of cerebral events of the details of which we are largely unconscious. In a similar way, a Jacksonian attack may represent the terminal stage of a complex cerebral action as well as the initial stage, and the persistence of the "habit" may be due to a persistence of a memory, more or less independent of the brain.¹ This reasoning would apply, of course, more especially to the Jacksonian types of idiopathic epilepsy, but there is room for question whether it does not apply, in some measure at least, to the cases of localized lesion as well, especially where a good many attacks have already occurred. Thus in Case 1 of this series, the hand fits, although they were sharply localized, even to the thumb and fourth finger, as a rule, and sensory in character, were often preceded by blurring of vision and strange feelings in the head. Everyone

has been inclined to admit that the longer the time during which the seizures due to localized irritation occur, the more widely the brain, as a whole, becomes involved, and although it has been amply proved that even after twenty years and more a suitable surgical operation may, in favorable cases, arrest the epileptic tendency, yet it is also pretty certain that the co-operative action of ever widening areas of the brain, or even of the brain as a whole, may show itself amost from the very outset, and this especially in children.¹ When this result has been reached, the case of the patient with traumatic or focal epilepsy probably differs but little, if at all, from that of a patient with idiopathic epilepsy. In other words, the epileptic tendency in his case has become one of the regular modes of activity of the whole brain, and the destruction of a single part, the hand center, for example, if it checks the seizures, must do so through some influence such as we are apt to classify as "inhibitory." If the gathering tension which precedes the epileptic outbreak had been in the habit of expressing itself through some motion or sensation of the hand, the tendency to this same mode of expression is likely to remain even after mutilation of the cortex, though susceptible of being checked at its source by inhibition or otherwise. If the fits go on, however, the motion or sensation which occurs after the destruction of a given center is likely to be more coarse in character and less sharply limited in extent than it was before that part of the delicate mechanism of the cortex had suffered damage.¹

In advocating the importance of the "inhibitory" and formation-of-new-habit theory of surgical operations in Jacksonian epilepsy, as against that which refers the benefits obtained to the removal of disease-foci, I do so not as maintaining that the former explanation is perfectly satisfactory or intelligible, but only that at the present moment it is the best one available. It has also the advantage that its provisional adoption encourages us to study and classify the cases of benefit from operations of other sorts, instead of passing them by with a shrug, and may thus lead to more profitable modes of treatment of analogous sorts.

As a step in this direction, the fact deserves mention that Eulenburg¹ in his interesting discussion of some of these points in 1895, in connection with the report of a case where the epileptic attacks held off for three years after a cortical excision and then returned, has a good word to say for the striking observations of Wetterstrand on the treatment of epilepsy through hypnotic suggestion. This mode of treatment is theoretically justifiable, since it is as reasonable to believe that epilepsy may be influenced favorably by one sort of mental attitude as that it may be influenced unfavorably by another, and the latter has always been accepted as a true sequence.

The natural history of all the neuroses and psychoses is, indeed, marked by a tendency to the occurrence, under favorable conditions, of periods of cessation of symptoms. Tic douloureux and mi-

graine are cases in point, but there are many others. There is such a thing as temporary "set" or "cyclic" action in the nervous functions analogous to the vortex-tendency, which sets up the ever-forming and dissolving eddies on a swift stream. These temporary inertia—or habit—vortices may work for good or evil, and it is on the possibility that the formation of one tending to good may be encouraged that a large part of the hopefulness of therapeutic endeavor is based.

It is possible, of course, that the manifold operations which have been done for epilepsy and have been attended with a considerable measure of success, sometimes do good in one way, sometimes in another. But the mind instinctively and justly seeks to cling to a single explanation as long as possible, and it would be fair to urge that if the excision of the apparently healthy (even though really slightly diseased) cortex effected its results on a wholly different and more rational principle from other operations, these results would be distinctly better, which, in fact, they do not seem to be.

It is common to see the inference drawn that because the cessation of certain clinical symptoms follows a given therapeutic measure, therefore the cause of the symptoms has been discovered. This is the diagnostic argument "ex juvantibus," and it reappears in a thousand forms. In fact, this reasoning is misleading and fallacious. The morbid cycle of disease, especially if this takes the form of a neurosis, whether epilepsy, asthma, Graves's disease, or any other, may often be broken in upon and dispelled by influences and impressions which had nothing to do with its formation, and this is another justification for the doubt whether a cessation of fits following an operation for excision of a supposed disease-focus in the cortex proves, or even strongly indicates, that we thereby remove the original cause of the disease. I would remark in passing that the presence of the localized meningitis discovered in three of the above cases, as in several others which are on record, not to speak of that which had developed (possibly as the result of meningeal hemorrhage) during the typhoid fever, in Case 1, seems to me of distinct clinical interest. It is not commonly accepted that this lesion is apt to follow such injuries to the head, as these patients describe, or to occur from such illnesses as those from which they had suffered.

Reasoning from the conditions above stated, I believe that the arrest of epilepsy through surgical operation is an affair primarily of inhibition, and next of the establishment of a new habit, made possible by this temporary arrest of the morbid outbreaks. I do not believe that it is necessary to look for a focal lesion to account for focal symptoms, any more than it is necessary to look for a focal lesion to account for the numbness of the hand or the hemianopsia which usher in an attack of migraine.

If this reasoning is correct, the therapeutic problem is how best to secure this inhibitory action. Cortical excision may be the most effective means to this end, but it sometimes leaves the patient with an embarrassing and persistent awkwardness of movement, and should therefore not be undertaken if other means will serve, which are not open to the same objection. Clinical observation and labora-

¹ Cf. Chipault, *Travaux de Neurologie Chirurgicale*, April-July, 1900; abstract in *Jr. of Nervous and Mental Dis.*, April, 1900.

¹ Cf. Eulenburg, *Berl. Kl. W. Schr.*, 1895.

tory experiment seem to indicate that even a simple exposure of the cortex may damage its nutrition enough to cause temporary paralysis of sensation and motion, in many cases, yet without inducing permanent impairment of function of serious amount, and any one who will take pains to look over a large number of important cases will see that not only the moderate degree of success observed by Dr. Warren and myself, but occasionally a much greater degree is obtainable in this way. The cause of the temporary disturbance of motion and sensation which follows simple exposure of the cortex is attributed by Hitzig to the occurrence of punctate hemorrhages deep in the cortex, and to edema and anemia of the brain, partly resulting from its being pressed into the trephine opening by the uncompensated action of the cerebral circulation, the counter pressure of the cerebral spinal fluid in the sub-dural space having been removed. This counter-pressure may, he thinks, be re-established if the excised bone is replaced in its old position, as by the Wagner bone-flap method of opening the skull for operations of this sort, which is now so common. Even with this precaution, however, it is probably a long time before the circulation and nutritive conditions in the exposed cortex become normal, if, indeed, this ever happens.

An advantage of this operation of simple exposure of the cortex is that it can be repeated if necessary, and that it does not shut out the possibility of doing excision of the cortex later. But whatever operation is done it should, in my opinion, be considered that the arrest of the symptoms is mainly useful as affording a better opportunity for bromide medication, and this opportunity should be taken advantage of energetically. It is not necessary to consider here the details of the bromide treatment, but, in fact, I believe that the best method is that originally proposed by Charcot and recommended by Tourette in a recent paper, according to which the dose is increased for three weeks, then dropped to the starting point, and then increased again, and so on. The bromide treatment should also be reinforced by every hygienic influence that can be devised.

As regards the question of the physiology of the cerebral cortex, the tendency of the more recent researches has been on the whole confirmatory of the generalizations of Goltz, and we must now cease to regard the cortex of the brain as a mosaic of specialized centers, and consider it rather as a net-work, standing as the expression of closely inter-dependent functions. Furthermore, real light has now been shed upon the vexed question of the relationship between consciousness and the brain, and upon the part which each plays in producing the phenomena of life and disease. In confirmation of these statements, I will refer to the investigations and interpretations of J. Richard Ewald,¹ of Loeb,² of Hitzig,³ and of the psychologist, Bergson.⁴ Ewald managed to arrange the conditions of his experiment in such a way that the surface of the brain of dogs could be excited here and there long after the shock of the first trephining operation had passed away

and while the animals were running about in perfect health and indifference. Under these circumstances he found it possible to excite localized movements of various sorts by electrical stimulation at points quite removed from any corresponding "center," and he points out that, in fact, arrangements *must* exist for uniting closely the functions of such a part as the hand with those of the eye and ear as well as the touch. He shows that the strong tendency towards recovery from the effects of local destruction of the cortex ordinarily implies the preservation of the semi-circular canals in the labyrinth, and that where these have been removed the recovery is incomplete or does not occur. These facts are best explained, he believes, under the view that the semi-circular canals have the function of maintaining a general muscular tonus, and that this provides a sort of compensation for the loss of the tactile (or mainly tactile) functions of the Rolandic convolutions, like that obtained through the action of vision in tabes.

The cortex of the brain is a great net-work, an immense telephone switch-board, by means of which the individual seeks, as best he can, to place himself in active relations with his environment. The sense of his desires and needs in the way of recognition and expression is a possession of his whole brain, and a possession which he will struggle hard to maintain, and which cannot be excised through mutilation of any small portion of the cortex. If you damage his switchboard at one point, you may make it more difficult for him to accomplish certain results, but unless the damage be too great, accomplish it he will, if only in a roundabout fashion, by a process of readjustment which will begin to assert itself as surely and as promptly as that which makes the epidermis begin to grow again upon the abraded skin. It is reasonable to suppose that the hand-center is also a center, in a feeble degree, for the arm, the face, the shoulder and the leg, and it is fair to suspect, although the fact has not, I believe, been proved, that if a sufficiently delicate test were employed, it would be found that even feeble electrical excitations of this area, like movements of the hand itself in health, would be attended by feeble contractions of the muscles which fix the root of the limb. And, conversely, after excision of the apparent hand-center, the readjustment which asserts itself forces the mechanism which had previously been correlated principally for coarser movements of the arm to substitute itself for that which had been destroyed. It is certainly true, to use the term employed by Loeb, that the problem of the cerebral activity is one that is rather dynamical than anatomical. It is like the case of a quantity of water which had stood in a complicated system of tubes, gradually finding a new level when one of the tubes is taken away. The dynamic excitability, if the expression is permissible, of the parts next related to that which had been previously in use, needs only to be raised to the necessary point, for the old processes and functions to go on as before, at least after a fashion. The case is more or less like that of aphasia. It is true, namely, as Hughlings Jackson long ago pointed out, that, underlying the bizarre variations of the speech disturbance in different forms of aphasia, there is always a tendency

¹ Verh. des Congr. f. Int. Med., 1897, Vol. I, p. 247.

³ Arch. fuer Psych., 42, 1900.

⁴ Matière et Mémoire.

towards a readjustment of the language-function, of such a kind that this function is found at the end not to have been mutilated in parts so much as weakened as a whole. In the struggle for the re-establishment of a new equilibrium the *verb*, which expresses action and has a wider hold on the individual's life of relation to his environment will always be recovered first. The proper names, which stand alone, will be recovered last.

In other words, if the individual can no longer present just the same front to the world as before, he will, nevertheless, present, so far as possible, the same *sort* of front.

It is interesting and important to note that this principle which underlies the readjustment of the cerebral functions, after injury or disease, on a plan modelled on the conditions of health, is essentially the same with that which underlies the readjustments in the case of the hysterical patient, only here the process is seen in an exaggerated, often grotesque form. Take, for example, the case of the anesthasias of cerebral origin. The modern French view has recently been expressed with admirable clearness by Verger (1) that in all cases where complete hemianesthesia is present this is to be regarded as a sign of hysteria, though perhaps grafted on to the symptoms of an organic lesion of the brain. On the other hand, the anesthesia to which a structural lesion of the brain gives rise in its own right, i. e., when uncomplicated by hysteria, does not, he thinks, occupy one whole half of the body, but only the extremities, where it gradually increases in intensity toward the distal end. I desire now to point out that, although these peculiarities of distribution are doubtless of clinical importance, yet the two conditions which we call, respectively, hysterical and organic, resemble each other in the respect that neither of the forms of readjustment of the sensory functions seen in them proceeds on anatomical lines, but both are examples of the re-establishment of an equilibrium for functional ends, for the benefit of the individual as a whole. It is, again, an affair of dynamics, and not of anatomy.

Just as in aphasia a patient is apt to lose his isolated names first and to retain his verbs the longest, so, when his sensori-motor cortex is injured he retains the more fundamental use of his limb and loses the luxury-functions of the hand and sometimes the sensory functions which are associated with the motor functions of this type. I maintain that this is precisely the ground on which the hysterical patient is supposed to lose and to retain, as the case may be, the sensory functions of his skin and special senses. There is a difference between the two sets of cases, but the underlying principle of readjustment is the same.

It is a merit of this mode of regarding the brain functions in disease that it brings out the dynamic, self-adjustible, so-to-speak "fluid," properties of that organ, and contradicts the tendency to represent it as an inflexible mechanism. It contradicts also the erroneous theory of the "storage of memories" in the cortex (1) subject to being destroyed piecemeal by disease. It is just because memories exist (in a certain sense) independently

of brain-action, that they cannot be thus destroyed, and that the marvelous readjustment of the functions of the damaged brain on the old lines of health, is able to occur.

It is also of interest to note that Hitzig believes, on the basis of a long series of experiments, that he has demonstrated the existence of a visual center in the frontal lobe, of analogous significance to that in the angular gyrus. Thus, provision is made for movements of the eye and for vision in two widely different portions of the brain. Neither of these centers seem to be, according to Hitzig, primary centers of vision, both stand in a similar relation to some more fundamental visual area.

WHAT I HAVE LEARNED FROM ONE HUNDRED AND SIXTY-ONE OPERATIONS FOR THE RELIEF OF SENILE HYPERTROPHY OF THE PROSTATE GLAND.

By ORVILLE HORWITZ, B. S., M. D.,

of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College;
Surgeon to the Philadelphia Hospital, Jefferson Medical College
Hospital and State Hospital for the Insane.

[Conclusion.]

Twelve cases were operated upon, four being complicated with pyelitis; in all there was chronic cystitis associated with either atonied or contracted bladder. Four had previously submitted to castration without benefit. The period of convalescence ranged from three to five months, including, of course, the care and necessary after-treatment. After the operation the individuals were respectively confined to bed for a period of from one to four weeks. In complicated cases of the character here described urethral fever is a very common occurrence. Five of these patients had been subject to chronic urinary fever for many weeks prior to coming under my observation. Three cases were markedly benefited and practically might be considered cured; though a small quantity of residual urine and a slight amount of cystitis still exist. In seven cases the bladder did not regain its tone, and the continued use of the catheter became necessary. The insertion of the instrument was rendered easy and painless; prostatic spasm, one of the most painful symptoms, being relieved. In four cases there was marked improvement in the general condition, indicated by increased strength and gain in weight. Of the remaining cases no improvement in the physical condition resulted. In the unimproved cases the trouble had existed for such a length of time and the damage to the bladder and kidneys was so great, that only an amelioration of the urgent symptoms could be hoped for. In this group the age was so great and physical condition was such that a complete prostatectomy could not have been performed with safety.

These cases seem to demonstrate that in prostatic hypertrophy the earlier the operation is performed the greater are the chances of permanent cure, danger to life being lessened, and but a short time for convalescence being required, and also that the operation may be undertaken in advanced cases

where secondary pathological changes have taken place with less risk to life and with better chances of relief than any other radical method in vogue at the present time. When castration had been performed the Bottini operation was followed by relief to the obstructive symptoms. Pyelitis is not a contra-indication to the performance of the operation, as in four of the individuals who submitted to this process this condition pertained and no injurious result followed. When the bladder is hopelessly damaged and polyuria exists, the operation will be followed by benefit, but cure is not to be looked for. Of the number of cases of this kind operated upon, in sixteen the enlargement was of the fibroid variety; four were glandular, and thirteen were of a mixed type. I have found that both success and failure will follow operations where any of the varieties mentioned exist. Hence, I believe that the character of the growth has little or no influence on the results obtained. If there is any difference it is in favor of the fibrous form. Good, as well as poor, results have been obtained by many surgeons, when operating upon either the hard or soft variety of prostatic hypertrophy; which seems to prove that the character of the growth has but little influence on either the failure or success of surgical procedure. The results obtained in cases where incomplete or complete retention of urine existed were about equal; if a difference subsisted it was in favor of the former condition. The beneficial results to be obtained from the operation seem to depend upon the amount of damage that the bladder has sustained, and whether or not the kidneys are involved, and also the physical condition of the individual at the time. The longest period that any of the patients had employed a catheter was fourteen years; the shortest two and a half months. In four of the cases catheterism had never been employed; in six individuals there was frequent urination, the residual fluid varying from two to eight ounces. In fourteen, catheterism was necessary from three to five times daily. Five of the patients had suffered from attacks of retention of urine from time to time. In nine cases the individuals were unable to evacuate the contents of the bladder without the use of a catheter. In six patients in whom benefit was derived from the operation the obstructive symptoms were so far ameliorated that a catheter could be readily inserted, without pain; physical spasm was relieved, and, as has been pointed out by Willymeyer, obstinate constipation, which is associated with this condition, disappeared. There was invariably an improvement in the physical condition as was shown by increase in weight and strength. Five of the cases here referred to were operated upon twice, and one underwent the procedure three times.

Regarding the length of time which should be allowed to elapse before repeating the operation, no fixed rule can be given. It depends on the character of the obstruction; the condition of the patient; the results following the first operation and whether or not there is a tendency to the recurrence of the obstructive symptoms after a lapse of a few months. I have repeated the process as early as three weeks and as late as six months after the first procedure, using my experience and judgment

as guides. Dribbling followed the operation in four instances; this state continued for about five days, then disappeared, giving no further trouble. The only other complications observed were prostatitis and urinary fever. The former occurred in five instances, giving rise to pain, frequent desire to micturate, with retention of urine, which usually subsided with proper treatment in the course of a week or thereabout. In the latter, especially in those who had suffered from urethral fever associated with a co-existing pyelitis and polyuria, preceding the operation, chill followed by a fever of a septic type was often an alarming symptom. From ten days to two weeks after the operation the urine was frequently tinged with blood, and contained threads of tissue and other debris. In no instance did hemorrhage occur. In three cases a stricture of small calibre was found in connection with the prostatic obstruction; in these internal urethrotomy was performed before inserting the prostatic incisor. In four cases preliminary suprapubic lithotomy was performed. In one instance the Bottini operation was accomplished as soon as the calculi had been removed, so that I had an opportunity of observing the result of the incisions immediately after the galvano-cautery had been employed. On examination it was found that a deep groove had been burned in the median line of the middle lobe, which entirely removed the obstruction and brought the internal urethral orifice down to a level with the base of the bladder. The incisions in both lateral lobes were well marked. In making the left lateral cut the knife had apparently slipped into the groove made in the middle lobe, and had incised the left lobe at its lower portion, in the vicinity of the base of the bladder. In one case I had the opportunity of performing a suprapubic cystotomy on a patient who had submitted to a Bottini operation seven months previously. I found that there was a deep furrow in the median line of the middle lobe; that the vesical outlet was at the normal level, and that all obstructions were apparently removed. The lateral lobes were hard and contracted, with evidence of dense cicatricial tissue. When a suprapubic lithotomy is necessary, arising from prostatic hypertrophy, I believe the wisest plan is to be content with removing the stone, and defer the operation until the patient has entirely convalesced. I have seen death follow the performance of the double operation. When a suprapubic fistula exists, it is well to postpone the Bottini operation until the sinus is closed. When the opening exists it is impossible to distend the bladder, rendering danger of injuring the walls very great; moreover, the sloughs and debris which always follow cauterization of the prostate are but poorly expelled. Recently certain surgeons have advocated the opening of the bladder suprapubically in order that the character of the obstructing prostate may be correctly determined and the beak of the instrument placed in the exact position desired. This procedure does not seem to me to be necessary. Everyone should be able to diagnose the character of the enlargement and the cause of the obstruction in prostatic hypertrophy by means of rectal manipulation; the increased length of the urethra, together with an examination of the vesical aspect of the gland, can be readily deter-

mined by the employment of the stone searcher and the cystoscope. The preliminary suprapubic cystotomy in these cases is believed to be unnecessary and needlessly adds to the danger attending the operation. Fear has been expressed by various writers that the use of the galvano-cautery might be followed later by a constriction of the vesical outlet, with resulting stricture. Three years have elapsed since my first operation was performed, and in no instance has any difficulty of this kind arisen. I believe the apprehension felt regarding this suggested complication to be groundless. Care should always be taken to properly prepare the patient to endure the operation. In several cases the patient was kept under preparatory treatment for three months before he was considered to be in a fit condition to undergo the operation. In some of the cases the prostatic urethra was so greatly contracted that even a small sized catheter could with difficulty be inserted. It was found that by leaving the catheter "à demeure" for a period of two weeks, passing small bougies about every third day, that the prostatic incisor could be successfully passed. In several instances, when the constriction was so well marked that the insertion of an instrument was impossible, it was observed that by placing the hips of the patient on an ordinary bedpan, thereby arching the body, that the curve of the urethra would be so much changed that the instrument could be readily passed.

When it is desired to employ general anesthesia an attempt should be made to insert the instrument a day or two previous to the operation, so as to be assured that it can be made to enter the bladder otherwise the individual might be etherized unnecessarily. A careful examination for the presence of calculus should always be made before the operation is undertaken. Employment of the cystoscope as a routine method of making an examination is not necessary. Its use is frequently attended with pain and discomfort and its employment is not free from danger if the kidneys be extensively diseased. Its use should be reserved for exceptional cases, where the existing local condition is difficult to determine. The employment of the Wossidlo cystoscopic prostatic incisor has been found to be valueless. Its use is not recommended.

Whenever the condition of the patient permits the use of general anesthesia is advisable, either being employed for the purpose. Many of the operations were performed by means of local anesthesia, a 4% solution of cocain being used. In nervous and excitable patients, who dread an operation and complain whenever an effort is made to insert an instrument into the urethra, spinal anesthesia is the method of choice. A means of anesthetizing the bladder has recently been suggested by Dr. du Chas-telet (*Ann. d. Mal. Org. Genito-Uri.*, No. 7, 1899) which is worthy of trial. It consists in injecting into the rectum forty-five minutes before the operation, a solution containing ten drops of laudanum and twenty-four grains of antipyrin, which has been dissolved in three ounces of water. It is claimed by the operator that by the use of this mixture in the manner described he was enabled to spend half an hour in crushing a calculus without discomfort to the patient.

My first two operations were successfully performed when the bladder was empty. Dr. Freudenberg recounts in detail the result of operating upon a patient when the viscus was empty, in which he was so unfortunate as to immesh a fold of the mucous membrane between the heated platinum blade and the prostate gland, thereby burning a hole through the walls of the bladder; this was followed by extravasation of urine and the death of the patient. He advises that a warm solution of boric acid be employed, wherewith to distend the bladder. In six cases following the two to which I have referred I followed the suggestion with favorable results.

In the *Medical Record* for November, 1898, there is an article by Bransford Lewis, in which he recommends that the bladder be inflated with air as a safe and satisfactory means of preventing injury to the walls of the organ. In all the subsequent operations to these to which I have just referred I have followed the recommendation of Lewis and have employed air wherewith to distend the viscus and have had every reason to be satisfied with the results. One of the most important adjuncts in the steps of the operation is to have on hand a battery that will promptly bring the knife to a white heat. For this purpose there is nothing more satisfactory, than the street current connected with a "transformer" which has an Ampere meter also introduced into the circuit. The best battery that can be used is the one advocated by Willymeyer, which, in addition to a rheostat, is connected with an Ampere meter. Fifty Amperes are required to heat the blade and maintain it at a white heat. In five instances the blade of the instrument become slightly bent during the operation, rendering it impossible to return it completely within the sheath; so that the removal of the instrument was attended with a slight amount of injury to the urethra, but in no case did any detrimental result follow the accident. The bending is caused by using the blade for the purpose of making the second and third cut before the whole of the adherent charred prostatic tissue has been burnt off. When the subsequent cuts are attempted, the portion of the glandular structure adherent to the knife serves to cause sufficient resistance to the blade, when it is softened by being brought to a white heat, to occasion its bending. This annoying incident can be obviated by removing the instrument after the first incision has been made and burning off the adherent tissue, leaving the blade clear and clean, and then re-inserting it in order to make the second cut. This should be repeated after each incision. That the burnt tissue, which is adherent to the knife, interferes with the incision is evidenced by the fact that the last cut is harder to make and takes longer to accomplish than any of those that precede. On removing the instrument it will frequently be found that a full minute is required to burn off the unconsumed portion of tissue which adheres to its blade. That the cut may be properly made and that the tendency to primary hemorrhage may be lessened it is necessary that the knife should be at a white heat. If it is found that fifteen seconds are required to heat the blade before the instrument is inserted, at least ten additional seconds

should be allowed to elapse after the instrument is in place before an attempt is made to make the incision. A certain percentage of failures is due to the fact that the cuts are made too rapidly. In my earlier operations about one minute and a half was taken for each incision. I am convinced that I have obtained better results when I have allowed from 3 to 4 minutes for making each cut. They should be made very slowly, as if the knife were passing through a substance offering great resistance; when it is finished and the blade is being restored to the sheath, it is well to have the current made somewhat stronger, the blade should be returned very slowly so as to insure the consumption of the portion of tissue that may be adherent to the knife. It is essential that the instrument be held firmly and steadily whilst it is being used. This may be insured by the operator placing his left foot on a chair in front of him and resting the elbow of the left arm upon his knee; as the left hand holds the instrument during the operation the danger of shaking or jarring is reduced to a minimum.

The number and length of the incisions will depend on the size, as well as the character, of the enlarged gland. In cases of commencing prostatic hypertrophy, where the organ is comparatively small, a median and two lateral incisions are all that are required. In cases of long standing, where the gland has attained considerable dimensions, three cuts on the prostatic floor should be made; the median being from three and a half to four centimeters, whilst two and a half centimeters are allowed for each lobe, unless one should be markedly enlarged when the cut should be proportionately increased in length. In every case that came under my control, with two exceptions, the incisions were made on the lower portion of the gland. In the two cases referred to there was general glandular enlargement, marked projection backward, with two pouches, one above and one below. In these cases one upper and three lower cuts were made. The upper incision is seldom necessary, and should be avoided if possible. In many of the cases where hemorrhage has been reported as one of the immediate complications following the operation it was probably caused by the incision being made in the upper portion of the gland. The reason for this becomes evident when the fact is recalled that the prostatic urethra is one-third nearer the upper than the lower portion of the gland; in some instances the prostatic tissue is absent for a short distance on the roof of the urethra, its place being occupied by a fibrous and elastic tissue. It follows, therefore, that an incision made on the roof of the prostatic urethra is more liable to injure the prostatic plexus of veins, which lies between the outer and inner capsule of the gland, than when the incision is made on the lower surface. When a marked projection of the middle lobe backwards exists, four cuts should be made in the lower portion of the gland. Two V-shaped incisions should be made through the middle lobe, which permits it to fall back out of the way, finally becoming shrivelled and atrophied; the lateral cuts are then made in the usual manner. After the instrument is in place, before proceeding to make the incision, the index finger of the left hand should be inserted into the

rectum, so as to determine whether the beak of the instrument is in the proper position, and, at the same time, to be sure that a fold of the bladder has not been entangled. The expedient which has been suggested of inserting the finger into the rectum and pushing the prostate gland up against the blade of the knife during the operation is not free from danger, as a recto-vesical fistula might result. It was not found necessary to leave a catheter in the bladder after the completion of the operation, except in those patients who had suffered from chronic cystitis associated with contracted bladder, or where they had long been affected with retention of urine. In two of the cases after the completion of the operation symptoms of uremia, with a marked tendency to suppression of urine, was developed. From these patients about four ounces of blood were abstracted from the vein of the arm, and immediately after this was followed by a venous transfusion of normal salt solution. Two and a half pints were transfused, which was repeated in the course of eight hours, as the dangerous symptoms had not undergone amelioration. Both patients recovered. A one-twentieth of a grain of digitalin combined with the same amount of strychnia was administered every third hour, the action on the heart being carefully watched.

Out of the number of patients operated upon, in three there was a slight tendency to the recurrence of the obstructive symptoms at the end of six months, making a second operation necessary. Two had occasional attacks of congestion of the prostate gland associated with temporary retention of urine following prolonged dissipation and exposure. From the results obtained by the experience that I have here recorded I feel that I am warranted in forming the conclusions here set forth:

1. Success following the Bottini operation depends on having perfect instruments; a good battery; the necessary skill, and the employment of a proper technique.
 2. In suitable cases the Bottini is the safest and best radical operation thus far advised for the relief of prostatic hypertrophy.
 3. It is often very efficacious in advanced cases of obstruction as a palliative measure, rendering catheterism easy and painless, relieving spasm; lessening the tendency to constipation, and improving the general health.
 4. It is of especial service in the beginning of obstructive symptoms due to hypertrophy of the prostate gland, and may be regarded as a means of preventing catheter life.
 5. It is indicated in all forms of hypertrophy except where there is a valvular formation, or where there is an enormous overgrowth of the three lobes associated with tumor formation giving rise to a pouch, both above and below the prostate gland.
 6. Where the bladder is hopelessly damaged, together with a general atheromatous condition of the blood vessels, associated with polyuria, results are negative.
 7. Pyelitis is not a contra-indication to a resort to the operation.
 8. The character of the prostatic growth has no bearing on the results of the operation.
- The ligation of the internal iliac arteries for the

relief of hypertrophy of the prostate gland, first recommended by Bier, has been tried by several surgeons with very unfavorable results. The benefit derived from the operation is slight, and the mortality higher than that following prostatectomy. Thus far, the results derived from agoneurectomy have been negative. I have frequently witnessed the operation of perineal prostatectomy when performed by others, and have on various occasions resorted to it, but I have found that nothing was gained beyond the temporary improvement that might naturally be expected to follow rest and drainage. These methods have, therefore, not been employed in the cases referred to in this paper.

WIENER KLINISCHE WOCHENSCHRIFT.

April 11, 1901. (XIV Jahrgang, No. 15.)

1. The Poisonous Effect of Alcohol in Certain Nervous Diseases. WAGNER von JAUREGG.
2. Alcohol and Insanity. JOSEF A. HIRSCHL.
3. Carbonic Acid Gas Applied Locally for Disturbances of Menstruation. Gustav Loimann.

1.—Alcohol does not affect all people alike. Yet it acts as a poison upon the nervous system, whether by an effect upon the nerve centers, or upon their blood supply. Individual disposition will influence the occurrence of delirium tremens which is seen only after long continued alcoholism. Wagner von Jauregg believes that in chronic alcoholism a poison is produced in the body under the effect of the alcohol, causing tremor, vomiting, delirium, etc., a poison which is undoubtedly due to the alcohol, yet it is not the alcohol itself, as more alcohol will cause the disappearance of the symptoms. Its real effect is seen after the alcohol has all been excreted. This he calls an **alcohologenous poison**. It resembles the poisons of bacterial origin seen in the infectious diseases. Leucocytosis occurs, with an increase in the polynuclear and a decrease in the mononuclear leucocytes, with the sudden appearance of eosinophilic cells after the delirium is over. Then the polynuclear leucocytes decrease and the mononuclear leucocytes increase relatively, while the eosinophiles may reach an abnormal amount. These changes in the blood are much like those seen in croupous pneumonia. Albuminuria also is seen. This poison has its maximum effect when no alcohol is taken. He advises continuing enough alcohol to prevent delirium, decreasing the amount gradually. **Polyneuritis** and the **polyneuritic psychoses** are also explained as the effect of this alcohologenous poison, just as they can be caused by the infectious diseases. As alcohol also causes indigestion, it acts as a double cause for the polyneuritic psychoses. But it is possible that from the deleterious influence of the alcohol upon the liver, secondary poisons are elaborated in the liver which, entering the circulation, cause these psychic manifestations. [M. O.]

2.—Of the total number of insane patients brought to the Vienna General Hospital, 30% of the men gave a history of chronic alcoholism. In a third of all insane men admitted, then, alcohol was an etiological factor. Among the women only 4.4% were alcoholic. The diseases most dependent upon alcohol were **epilepsy**, **paralytic dementia**, and **senile insanity**. In all cases alcohol was absolutely withdrawn, except, rarely, in delirium tremens with cardiac complications. 4.3% of the alcoholic cases died from delirium tremens. 28% of these alcoholics had to be confined in insane asylums for the rest of their lives. Hirschl, in closing, shows that the cost of supporting the alcoholic insane is far greater than is the income derived by the government from the liquor tax, to say nothing of the injury done to health, morals, and society by the excessive use of alcohol. [M. O.]

3.—In the second half of the eighteenth century, **carbonic acid gas** was first used locally in baths and douches. Loimann has seen excellent results from its use in the disturbances which accompany menstruation, dysmenorrhea, oligomenorrhea, and amenorrhea. Most of the towns which boast of carbonic acid waters have arrangements for giving carbonic acid gas baths. As the gas penetrates the clothing, it is unnecessary to undress. Vaginal douches

may also be given. Loimann has devised a practical contrivance for carbonic acid gas douches. The mucous membrane of the uterus becomes reddened, with a great increase in the secretion. Menstruation generally appears earlier and more copiously than usual, after repeated douches of carbonic acid gas. Especially are those women, who show no abnormality of the genitalia, successfully treated. Even if the mucous membrane of the uterus be altered, carbonic acid gas douches may cause the appearance of menstruation. It must not, however, be attempted during pregnancy, or abortion will occur. [M. O.]

JOURNAL DE MEDICINE DE BORDEAUX.

March 31, 1901. (31me. Année, No. 13.)

1. The Dispensary for Children in Bordeaux. EUGENE QUINTRIE.

1.—The first infant dispensary in Paris was opened in 1892, by Professor Budin. Since then nine more have been established in Paris, and two in the provinces. Dr. Saint-Philippe started this one in Bordeaux in 1899. The dispensary is open once a week for directing infant feeding. The children with contagious diseases are at once separated from the others. As the mothers are generally very young, and unmarried, it was a great effort to interest them in their own infants. That the children benefited from the physicians' advice finally made the dispensary a success. All babies were weighed at the first visit, and monthly afterward. A complete history of the mother's past is obtained, especially of venereal troubles. Histories of the father are as a rule very vague or impossible. Signs of tuberculosis and syphilis are always sought; malformations in the infant and the condition of the mother's breasts are fully noted. A printed list is given every mother, which explains the toilet of the child and its feeding. During the past two years almost 1000 infants have been treated. Two thirds of these infants were raised on the breast alone; one fifth on the breast and bottle; and over a tenth were bottle-fed, upon sterilized milk in small quantities. Babies were weaned from 12 to 14 months. At ten months, cow's milk, boiled, was begun, a cup full daily, and nothing given all night. From 14 months, they had milk at 8 A. M. and at 4 and 8 P. M., with soup, egg, bread, and boiled water at noon. In 1899, the death rate was only 4.4%; in 1900, only 2.2%. These results speak for themselves. It is to be hoped that more such dispensaries will be established throughout France. [M. O.]

The Role of the Leukocytes in the Absorption of Certain Medicines Introduced under the Skin and into the Peritoneal Cavity. Marie Louis René Montel. (*Gaz. Heb. de Med. et d. Chir.*, April 21, 1901. 48 me. Année. No. 32. *Bordeaux Thesis*, 1900-1901. No. 2.)

Montel has studied the method of absorption of calomel, iodoform oil and sodium salicylate. Calomel injected under the skin or into the peritoneum is for the most part taken up by the leukocytes either in the form of reduced mercury and sublimate or in the form of small crystals of calomel. Under the influence of the cellular activity of the leukocytes, calomel becomes changed into sublimate and reduced mercury. The nodules that result from the subcutaneous injection of calomel are due to a defensive process of the organism. Under the skin, as well as in the peritoneal cavity, calomel is absorbed during a stage of hyperleukocytosis due to a positive chemotaxis of the leukocytes which is preceded by a stage of hypoleukocytosis and negative chemotaxis. The stage of hypoleukocytosis varies in length depending upon the size of the injected dose. Hyperleukocytosis is the evolution towards cure, and it is the polymorphonuclear and the large mononuclear leukocytes that seize the mercurial salt. Iodoform oil is absorbed and transported by the leukocytes. This absorption seems to be due particularly to the large mononuclear elements. It is accompanied by marked hyperleukocytosis. In an animal who has received an hypodermic injection of sodium salicylate the white bloodcorpuscles treated by perchloride of iron are found to be studded with black points that indicate the formation of salicylate compounds of iron. For these different substances the absorption, almost exclusively cellular, is due to the leukocytes which, circulating in the blood current, are carried to the point at which their action is needed. [J. M. S.]

The Importance of the Hemolymph Glands.—

In 1884 H. Gibbes described the presence in the human subject of certain minute lymph glands found in the connective tissue between the renal artery and vein. They differ from lymph glands in the fact that they contain blood sinuses instead of lymph spaces. In 1890 W. F. Robertson described similar structures in the sheep and bullock, also mentioning their presence in man. He developed the histology of these organs which he named "hemolymph glands," and he called attention to the difficulty of distinguishing between lymph glands and hemolymph glands with the naked eye. Vincent and Harrison (1897) studied the hemolymph glands in animals. They pointed out that a lymph gland has only to contain blood in part, or all, of its tissues to be considered a variety of hemolymph gland, and made the important observation that there is a great resemblance between certain accessory spleens and hemolymph glands. W. B. Drummond made a careful study of these structures last year. He expressed the opinion that there is not sufficient evidence that they play an important part in the formation of red blood corpuscles. He believes that they take part in the destruction of these cells and in the liberation of the pigment, as well as being centers for the formation of leukocytes. A. S. Warthin has recently contributed a most valuable paper on this subject based upon the study of eighty autopsies on the human subject (*Journal of the Boston Society of Medical Sciences*, April 23, 1901). He has determined that these glands are found in greatest prevalence in the connective tissue of the retroperitoneal, prevertebral region, and that they are uncommon in the mediastinal tissues, or along the thoracic vertebra. They are found in considerable number in the cervical region, below and behind the lobes of the thyroid. These glands vary greatly in size and number. Warthin states that the ratios 1-20 to 1-50 express their relation with the lymph glands. The vascularity of the hemolymph glands is very remarkable at times, and they are found usually near large blood vessels. Microscopically, this author describes two types of hemolymph glands, to which he has given the names *splenolymph* gland and *marrowlymph* gland, as indicating their

structure and probable functions; but between these two types transition forms exist as well as between these glands and the spleen on the one hand, and ordinary lymph glands on the other. Warthin concludes that under normal conditions the hemolymph glands are chiefly concerned with hemolysis and leukocyte formation and play but little part in the formation of red blood cells. When, however, the blood shows marked changes a condition of these glands is present that indicates clearly their blood-forming function. The careful study of the retroperitoneal tissues reveals the fact that the lymphadenoid structures are constantly undergoing progressive and retrogressive changes. Warthin points out the intimate relationship existing between adipose tissue and lymphadenoid tissues, which is here shown strikingly; and the probable metaplasia of the former into the latter, as in the case of splenic anemia, confirms the observations of Bayer and Tizzoni. The intimate relationship existing also between the spleen, lymph glands, and bone marrow is indicated by the power of the hemolymph glands to assume the structure and function of these organs in certain pathological conditions. The fact that transition forms of cells between small lymphocytes and erythrocytes, as well as between hyaline mononuclear leukocytes, and nucleated red cells are found in these structures, seems to confirm the views of Löwit and Howell. The further study of the hemolymph glands promises rich results in contributing to our knowledge of blood formation, blood destruction, and the physiology and pathology of the blood-forming organs.

The Cases of Plague at Hull, England.—This outbreak was one of special instructiveness, particularly because of the masterful way in which it was managed. The steamship *Friary* left Alexandria on December 22, 1900, and touched at Algiers on December 30 (*Public Health Reports*). On December 31 she left Algiers and sailed direct for Hull, England, where she arrived on January 10, 1901. She had clean bills of health from both Alexandria and Algiers, the captain only having gone ashore at the latter port, although the ship took on coal there. On the voyage from Al-

giers to Hull one of the crew died two days before reaching port. Death was believed to be due to natural causes, and the body was interred in one of the Hull cemeteries. Then it was found that several of the crew were ill. The sick men presented rapid pulse, a temperature of about 101° F., headache and articular pains. It was first thought that the disease was influenza with lung complications. Two of these patients died, about forty-eight hours after they were taken ill, and, at autopsy, it was found that the cause of death in both cases was pneumonic plague. The diagnosis was confirmed, subsequently, by bacteriological examination. The ship was then moved to quarantine, about twelve miles from the city, and the patients were placed in isolation in a hospital four and one-half miles from the city. In this hospital eight out of the nine patients affected with the disease died. The mortality, however, was confined to the members of the crew who had lived in the fore-castle of the ship. Several rats were found dead in the hold of the ship during the discharge of the cargo, and members of the crew stated that they found dead rats on the vessel after leaving Alexandria. A cat that had lived in the fore-castle was taken sick and thrown overboard during the voyage. A dog that lived with the crew was also taken sick. This animal was killed, but bacteriological examination did not reveal plague bacilli. It is evidently entirely due to the energies of the port physician of Hull, Dr. Mason, that this epidemic of plague did not spread to the port and become generalized. The form of disease from which the infected members of the crew suffered was the form most difficult to diagnose and the most ready of propagation on account of the fact that the bacilli are thrown off in large numbers with the sputum. The fact, however, that this epidemic was confined to the ship on which it was imported is strong evidence that contagious diseases, the micro-organismal cause of which is known, can be satisfactorily treated and their spread prevented by modern methods. Furthermore, there is no reason why the inhabitants of a port into which a contagious disease, such as plague, may be brought, should become panic-stricken and adopt measures that tend rather to lessen than to advance efficient prophylaxis. The recent case of pneumonic plague that developed at Ann Arbor (Report of Proceedings of Association of American Physicians, *Philadelphia Medical Journal*, May 25, 1901) in a laboratory worker who was studying the bacillus pestis is further evidence that once plague is diagnosed its spread can be prevented by modern methods. The student in question, together with all those who had been associated with him, was isolated, and by the use of Yersin's serum, was cured, and no other

case of plague developed in the University of Michigan. The individuals who were exposed to plague at Hull, upward of sixty in number, were inoculated with Haffkine's prophylactic, but none of those actually ill appear to have been treated with Yersin's curative serum. The evidence points strongly to Yersin's serum as the only hope, once the disease has developed, and it seems possible that this serum might have resulted in saving the lives of some of those who perished in the Hull epidemic.

The Clergy and the Doctors.—The absolute inability of some religious writers to appreciate the real force and trend of the modern science of pathology, is curiously shown in their methods of criticising so-called Christian Science. They naturally fear this new cult for its effects on existing religious systems rather than for its menace to the public health and the public intelligence. In a recent contribution to the *Churchman*, a prominent Anglican divine discusses the relation of the early church to the treatment of disease. He thinks he finds evidence that the clergy in those remote times exercised the functions of the physician, but he adduces no adequate proof whatever in support of this claim, for it is not the function of the physician to cure by miracles and wonder-working. Lecky (*History of European Morals*, Vol. 1) has shown that the early church relied upon thaumaturgy, just as Christian Science is doing, whereas legitimate medicine does nothing of the sort. The *Churchman*, commenting on this paper, makes the astonishing statement that "many a clergyman is already a consulting physician." It seems to think that the two offices—that of the priest and that of the physician—should be combined in one and the same person. All this is evidently suggested by the progress of Christian Science, but the point of the whole matter is curiously missed.

These writers should at least understand that the whole therapeutic power of any religious system lies simply in the domain of mental impression or suggestive therapeutics; that this power is not, and never has been, confined to any one religion or sect, but has been exerted by all of them in every period of history and in every region of the globe in which they have prevailed; that this suggestive therapeutics is potent for good in only a limited domain of medical practice; and, finally, that suggestive therapeutics can just as well, if not better and more rationally, be used by extra-theological methods. The Hindoos and the Chinese, as well as the ancient Greeks and Romans, have not been unfamiliar with the therapeutic value of religious emotion. This is shown by Regnier in his work on hypnotism in the ancient religions (*Hypnotisme et Croyances Anciennes*,

Paris, 1891), and by Nevius in his book on demon possessions in China (*Demon Possession and Allied Themes*, 1896).

To see in all this any evidence that the enormous fabric of modern medical science will be, or even can be, entrusted to the hands of the clergy (as seems to be the idea of a writer in the *Literary Digest*) is an evidence of a critical insight that would have done credit to a mediaeval monk.

Six Notable American Medical Achievements.—

In an interesting address recently delivered to the graduates of the Medical and Dental Departments of the Columbian University in Washington, Dr. G. E. de Schweinitz picked out for special distinction the work of six American doctors in medicine and surgery. These contributors to science, who have each done some epochal work, are Beaumont, for his work in gastric digestion; Gerhard, for his observations that led to the differentiation of typhoid and typhus fevers; Gross, for his pioneer work on pathological anatomy; Oliver Wendell Holmes, for his recognition of the contagiousness of puerperal fever; H. C. Wood, for his work in therapeutics; and S. Weir Mitchell, for his rest cure. This list might, as Dr. deSchweinitz justly says, be somewhat enlarged, and we should certainly not omit from it the names of Ephraim McDowell, who performed the first ovariectomy, and of that greatest benefactor of all, Morton, to whom the world owes the first practical demonstration of ether anesthesia. As Americans, we cannot too jealously guard the fame of Morton, for there has been at times some tendency to detract from the honor which is his. Dr. de Schweinitz's address was an eloquent plea for the originality of some of the best work that has marked the progress of medicine in America, and was especially appropriate to the occasion. American medical students and graduates cannot be taught too earnestly to respect the work of their own countrymen, and not to look abroad too exclusively for knowledge and initiative.

Aerophagia.—Aerophagia is the name given by Bouveret to a spasmodic swallowing of air, followed by frequent noisy eructations of gas, seen in hysteria (*Revue de Medecine*, 1891, p. 146). Pitres also found the condition in hysteria (*Progres Medical*, January, 1895). Lyonnet and Vincens, students of Bouveret's, have seen aerophagia with nervous dyspepsia, and call it false flatulence, due to the deglutition of air. (*Lyon Medical*, February 10, 1901.) At a meeting of the Medical Society of the Paris Hospitals (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, 1901, Nos. 8 and 9) Mathieu described the condition as a continual belching, with

much noise, some time after meals, accompanied by epigastric pain. He reports a number of cases in nervous dyspeptics, with enteroptosis and other gastric diseases. The patients soon realize that relief follows the swallowing of air, as that opens the cardiac orifice enough to allow the gas, the cause of the distention and pain, to escape. When once established, it soon becomes frequent. Vomiting occasionally results. Mathieu believes that a simple caution, in most cases, will cause its cure. With hysteria a more severe treatment will be necessary. The dyspepsia and enteroptosis should be treated in the usual manner. Siredey reported similar cases. Linossier separates distinctly the aerophagia of hysteria from that of dyspepsia. The former resembles rumination; for, when rumination occurs in man, it is begun by aerophagia, with eructation following. He considers aerophagia simply gaseous rumination. Le Noir stated that aerophagia was very common among horses. Soupault believes that aerophagia may be voluntary or involuntary. The former is seen among nervous dyspeptics, an interesting case of which is reported; the latter is seen in hysteria. Moderate aerophagia is also found with flatulent dyspepsia. Not only is will power a determining force in producing this loud belching, but tapping upon different regions of the abdomen also causes it. Rendu believes that aerophagia is always physiological, in no way pathological. Mathieu closed the discussion by showing his results, quick recovery, as soon as the patients understood that they could control the eructations. Both Mathieu and Soupault, who have studied the subject most thoroughly, insist that the treatment ordinarily given, carminatives, antiseptics, and absorbing powders, have absolutely no effect upon the condition.

The Accidents Accompanying the Eruption of the Permanent Teeth.—

The condition of the teeth has, in the past, been considered the sole concern of the dentists. But it may be stated with considerable degree of truth that the physician is quite as much interested in the phenomena of dentition as is the dentist. Hunter's articles, which have appeared lately, have called attention to the relation between oral sepsis and the general health, and now Audy (*Paris Thesis*, No. 252, *Gaz. Heb. de Med. et de Chirur.*, May 19, 1901), calls attention to the fact that the oral lesions that accompany the eruption of the permanent teeth, other than the third molars, are frequently of an infectious nature. He points out that in order to cure such lesions the same rules should be followed that apply to the treatment of infected wounds; free incision and local antisepsis. The most rigorous possible buc-

cal asepsis is the only method for the prevention of these infectious complications. Buccal asepsis necessarily includes brushing the teeth of children after they have reached the age of three or four years. We should be inclined, however, to advocate the institution of this sanitary arrangement at an earlier time in life than the third year. The production of painful and congestive lesions of the gums escapes all foresight. Nervous affections of reflex origin, which Audy has seen only imperfectly produced, evidently cannot be influenced by preventive treatment. It is undoubtedly the physician's duty to insist to all his patients, especially those in whom such matters are frequently neglected, upon the importance of the hygiene of the mouth.

The Pancreas of the Embryo and the New-born.

—It is strange that after all that has been written and done in infant feeding, our knowledge of the digestive physiology of infants is still very limited. The meagre information on the subject is represented mostly by a few theories based on *a priori* reasoning, deductions from the effects of various foods, or dogmatic statements made by a few authorities. It is assumed, and correctly so, that the natural food of infants is milk, *ergo*, the digestive organs of the infant must be such as to be adapted to the digestion of that particular food and no other; in other words, the ferments necessary for the digestion of starches must be absent. As a result of such reasoning, we have the stereotyped belief that the child, during the first few months of infantile life, possesses no amylolytic ferment. This belief, by the way, has been exploded by recent investigations which seem to prove that this is not the case. Dr. E. Garte took up the subject in an experimental way and brought to light some facts concerning the digestive functions of infants, which deserve special mention. The results of his work were embodied in a dissertation delivered before the Military Academy of St. Petersburg (summarized in the *Bohitchnaia Gazeta Botkina*, Vol. XII., No. 1). The author removed the pancreas from the dead bodies of new-born infants and placed it in physiologic salt solution for 24 hours in the incubator, adding thymol to exclude the action of bacteria. This antiseptic proved quite effectual, as shown by bacteriological examination of the infusion, which remained sterile. He then tested the action of this infusion of the pancreas on albumen, starch and fats. All these substances were digested, showing that the corresponding ferments are present in the pancreas of the new-born. Moreover, he found that these ferments make their appearance on the third month of intra-uterine life, and that the pancreatic juice is actually secreted on the fourth month, although the amylase in the new-born is four times less than

in the adult. The practical conclusion reached by the author is that the infant from its birth is able to digest small quantities of starch. In working with pathological material, he found that chronic diseases, irrespective of the location, have a more depressing influence on the pancreas than the acute. The following observations are of considerable interest from a biological standpoint: 1. A trypsin-like ferment was found in the liver, kidneys, spleen and lungs of the new-born. This ferment was already present in the above-named organs, especially the liver, on the sixth month of intrauterine life, proving that pancreatic juice is secreted and absorbed by the organs at this early period. 2. A diastatic ferment was found in all the organs and even in the skin of the abdomen. 3. There is no relation between the amount of glycogen and the diastatic ferment..

The Recreations of Scientists.—With men in our profession all seasons are times of work: therefore, all seasons for them are likely to be times also for play. How else can your poor overworked doctor (who is so apt to condole with himself) even things up? He must snatch his moments of sport even from the grasping hours of toil and duty. Who shall blame him for this? If he hurries from the sick room to a game of cards, he is not to be charged with cynicism and indifference. The season, such as that just passed, for the meetings of the numerous medical associations is the great recreation time for the doctors. There is no use in denying the fact; many a good man goes to the yearly meeting of his association with his mind bent on pleasure as well as on science. And we are not going to berate him for this in these columns. If we were a self-constituted reformer of the medical profession (which we are not), we might find occasion here for some labored editorial rhetoric. But a fellow feeling makes us wondrous kind, and we confess that the humorous side of this whole picture appeals strongly to us. That doctors should travel many hundreds of miles to attend a grave assemblage of their colleagues, and then should rush off from the meeting at a moment's notice to attend a horse-race or to take a ride on a river, strikes us as being peculiarly man-like. We recently saw a big base-ball match deplete an afternoon session of an association of specialists, many of whom are well known to fame. One unfortunate member confessed aloud that he would like to go with the sport-loving delegation, but could not, because he had to stay and read a paper. He was in the position of the small boy who would like to play truant but dares not. The man who would propose on such an occasion that the society adjourn in favor of the ball match would be frowned down. He would be judged guilty of levity and would be voted a Philistine. But the

man who deliberately gets up, takes his hat, and leads off a coterie of his weaker brethren to the neighboring ball field, is envied rather than scorned. And when one thinks that the bold man has come hundreds of miles and spent much money, one must at heart have a little sympathy with his desire to get some fun out of it all. And then, after all, the papers can be read just as well when they are published in the journals.

Reviews.

A System of Practical Therapeutics, Edited by Hobart Amory Hare, M. D., Prof. of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Physician to the Jefferson Medical College Hospital. Published by Messrs. Lea Brothers & Co., Philadelphia and New York. 1901.

The first volume of this valuable work was reviewed in a former number of this journal. Volume Second is devoted to fevers, diseases of the respiratory and circulatory system, diseases of the digestive system and kidneys, nervous diseases and diseases of the skin.

Dr. Hare, the editor, has written the chapter on typhoid fever. His comments upon the Brand treatment will be especially interesting to those who have been inclined to give this treatment their unqualified approval. Dr. Hare is apparently not one of the unqualified advocates of the Brand treatment. He takes care, however, to state in italics that he would have made himself misunderstood if any reader should consider that he was opposed to cold bathing in fever. The aim of his article is apparently to marshal all facts both for and against the treatment, and thus to draw scientific inductions. Dr. James N. Anders writes an article on malarial fevers and describes the treatment of that disease and its various conditions in great detail. Dr. William M. Welch, of Philadelphia, a well-recognized expert on smallpox, has written a most instructive chapter on that disease. The article on varicella by Dr. J. P. Crozer Griffith, on yellow fever by Dr. D. T. Laine, on influenza by Dr. Frederick A. Packard, and on diphtheria by Dr. Floyd M. Crandall, are a few of the chapters. The mere mention of the names of the authors is sufficient to guarantee the value and accuracy of their work. The chapter on diseases of the liver is written by Dr. John H. Musser, whose name is especially identified with this department of internal pathology. It is hardly fair in noticing such a valuable encyclopaedic work as this to merely mention the chapters and authors, but space here forbids a detailed review. In the treatment of nervous diseases the editor has made very judicious selections of writers. Thus, Dr. Sinkler writes on the treatment of headaches and neuralgia, Dr. Dercum on the drug habit, Dr. Patrick on disorders of sleep, Dr. Allen Starr on locomotor ataxia, Dr. Charles K. Mills on apoplexy and brain tumors, and Dr. Joseph Collins on spasmodic affections of the nervous system. The medical treatment and hospital treatment of insanity are described respectively by Dr. Bannister and Dr. Brush.

Volume Third is devoted to surgical technique, surgery of the genito-urinary apparatus, respiratory and digestive systems, fractures and dislocations, and anesthesia. It is thus seen that this volume is practically a treatise on surgical treatment. In this respect the work is a departure from mere works on therapeutics, and this departure is a decided gain to all practitioners and students who may resort to it for instruction. Among the well-known authorities whose work appears in this volume are Dr. William T. Belfield, Dr. Edward P. Davis, Dr. George R. Fowler, Dr. Charles M. Frazier, Dr. Andrew J. McCosh, Dr. Edward Martin, Dr. E. E. Montgomery, Dr. Henry R. Wharton and others. Dr. Leonard has written an unusually full chapter on anesthesia based upon a large clinical experience.

The article is accompanied by illustrations showing the different methods for artificial respiration.

Dr. Frazer describes in great detail surgical technique. Dr. Wharton has a chapter on the treatment of fractures and dislocations, which is of course a complete surgical paper on those subjects. Diseases of the rectum and anus are treated by Dr. Mathews; and the practical points in

minor surgery and bandaging are considered by Dr. Spencer. An interesting paper the one on cerebral concussions and shock, by Dr. Joseph Ransohoff; and empyema, which is a subject of so much joint interest to both physician and surgeon, is treated of very accurately by Dr. A. J. McCosh. Dr. Fowler has written a paper on appendicitis which is also nothing more nor less than a complete surgical paper on this subject. He does not ignore medical treatment, however. Dr. Martin has an unusually able paper on obstruction of the intestines, and Dr. Belfield has thoroughly discussed the infections of the genito-urinary tract in a very important paper. Dr. E. E. Montgomery, from his broad clinical experience, has contributed a most valuable paper on the genito-urinary diseases of women.

Dr. Davis writes on the therapeutics of pregnancy, parturition and the puerperal state with all the care and detail which always characterize his work. Dr. Wood has written a paper on the remedial agents in diseases of the eye as treated by the general practitioner. This volume concludes with special chapters on the diseases of the ear, by Dr. S. McC. Smith, the nasal chambers by Dr. E. F. Ingal's and the larynx by Dr. D. Braden Kyle. These chapters for thoroughness and scientific merit are in full accord with the general character of this important work. [J. H. L.]

Year Book of the United States Department of Agriculture, 1900. Published by the Government Printing Office.

This book, published by the United States Government, contains a great quantity of most valuable reading matter. Its contents are, of course, of primary importance to the agriculturist, but there are some interesting things in it that appeal directly and indirectly to medical readers.

We have noted especially the articles on the date-palm and its culture; on the food of nesting birds; on commercial pear culture; on practical forestry in the southern Appalachians; on the value of potatoes as food; on heat waves, and on some poisonous plants of northern cattle ranges. The several articles on birds are especially interesting and important. These are thoroughly scientific papers intended to show the useful work done by birds in our orchards, forests and fields in protecting trees and plants and thus directly protecting the farmer's and everybody's interests. These articles should be distributed broadcast. If they were more thoroughly known there might be some cessation of the cruel and useless destruction of bird life in this country. [J. H. L.]

Municipal Sanitation in the United States. By Charles V. Chapin, Superintendent of Health of the City of Providence. The Providence Press, Snow and Farnham, Providence, R. I. 1901.

This volume is the result of Dr. Chapin's long labors in the field of Sanitary Science. It is work which gradually grew from the material accumulating in his hands, and the information which it contains is of a decidedly practical character and will prove of great assistance to those interested in the subject of hygiene and sanitation, and especially to those whose duties pertain to Public Health. The volume is a comprehensive one, and while it does not pretend to cover the entire field of sanitary science, the information conveyed comprises a single volume of considerable size, some 950 pages. To give the reader an idea of the scope of Dr. Chapin's work, we might mention some of the general headings; such as, Sanitary Organization, Registration of Vital Statistics, Nuisances, Communicable Diseases, Dairy Products and Refuse Disposal. In the chapter upon Sanitary Organization will be found a valuable history of the development of such legislative regulation in the United States. In the second chapter on the Registration of Vital Statistics and the Disposal of the Dead, the author emphasizes the value of properly compiled statistics and furnishes the regulations demanded by the various States for the returns of births and deaths, together with the legal penalties involved in falsifying these returns. The chapter on the Disposal of the Dead deals especially with the regulations governing burial in the various States. The author discusses Nuisances and Specific Nuisances in two comprehensive chapters, and again furnishes his readers with the different State methods of the abatement of nuisances and the legislation governing the subject in general. The chapter upon Water, Ice and Sewage, dealing especially with the disposal of sewage and the pollution of streams, might be taken to heart by the citizens of many of our municipalities who will be put to

shame upon learning from these pages what advances sanitary science has made and all of which many have yet to put in practice.

The Adulteration of Foods, both Dairy Products and Food other than Dairy Products, comprises two interesting chapters which supplies valuable information not only as to the legislation governing food adulteration, but they are teeming with suggestions as to the proper methods of inspecting food-stuffs and especially measures for controlling the Dairy supply. We are not disappointed in the able and comprehensive manner in which the subject of Communicable Diseases are treated. The legislation, administrative work and the subject of Hospital Quarantine have received full consideration. The wide reading of this book would prove a valuable argument in the interests of preventive medicine. Many illustrations are given of excellent hospitals which have been built in various parts of the country for very small sums. The results achieved in controlling epidemics by following out the definite and well-known principles which this book expounds show the necessity for thoroughly grounding all those who have to do with the public health with just this information. The quarantine officer who reads this volume thoughtfully will be acquainted, not only with the regulations adopted in his own and other States, but with a thoroughly practical knowledge which will give him a vantage-point in dealing with the intricacies of the subject. The question of the disposal of refuse is taken up at length, and the various methods adopted by different municipalities are detailed. Grouped under Miscellaneous Work, we find the Communicable Diseases of Animals, the problem of School Hygiene, and Medical Inspection of Schools, as well as the Inspection of Buildings, including the laws governing the erection of sanitary buildings. In the appendix a large number of forms of permits and various blank forms pertaining to the various divisions of the board subject are given. We cannot conclude our review of this book without expressing our conviction that the work is one of great practical value, and that the immense amount of labor which the author has expended upon it has resulted in the production of an indispensable treatise which covers with judgment and commendable fullness the various departments of sanitary science. [T. L. C.]

Correspondence.

SUBSCRIPTION FOR MONUMENT TO THE LATE PROFESSOR OLLIER IN LYONS.

By DR. W. W. KEEN.

To the Editor of the Philadelphia Medical Journal:

Sometime since you kindly published an appeal of a Committee soliciting subscriptions for a monument to the late Prof. Ollier in Lyons. As Treasurer of the Committee, I beg that you will publish this letter in your journal in order to inform the profession that I have received the sum of \$649 from 193 subscribers. I have forwarded the same, less \$4.60 for postage, printing, etc., to Dr. G. Mondan, 27 rue Jarente, Lyons, France.

THE BRITISH CONGRESS ON TUBERCULOSIS.

By WILLIAM OSLER, of Baltimore.

To the Editor of the Philadelphia Medical Journal.

Dear Sir:—I should like, through your Journal, to call the attention of members of the profession to the important Congress on Tuberculosis, which will be held in London from July 23rd to 26th. It is much to be desired that a large contingent from the United States should participate in the work. Many prominent physicians have signified their intention of joining the Congress. Members of the profession wishing to do so should send their names, enclosing five dollars, to Dr. St. Clair Thomson, 20 Hanover Square, London, W., England.

Large Odontopathic Cysts of the Upper Jaw.—It is very rare to find a cyst as large as an orange at the root of a tooth in the upper jaw. Dr. J. Chaminade states in the (*Annales de la Polyclinique de Bordeaux*, 1901, No. 5). He reports two such cases in adults, originating from the roots of the smaller molar teeth of the upper jaw. In both cases these roots were removed, the cyst incised, curetted, and cauterized with tincture of iodine. There has been no recurrence in either case. The diagnosis from abscess is not difficult. The patient will rarely permit total extirpation of the cyst. [M. O.]

American News and Notes.

Dr. Henry C. Haden, Clinical Assistant in the out-patient department for diseases of the eye, at Jefferson Medical College Hospital, Philadelphia, at the recent tenth semi-annual meeting of the South Texas Medical Association read a paper before the section on Ophthalmology, entitled, *Exophoria; Its Significance and Treatment*.

Site for the Almshouse and Philadelphia Hospital.—It is stated that after viewing the places along the Delaware river front and hearing the views of leading physicians who accompanied the members on the trip of inspection, the Department of Charities and Correction agreed to recommend to the Mayor and City Councils that Petty's Island be purchased as a site for an almshouse and a hospital for the insane. It was suggested that a maternity hospital, a home for foundlings and a hospital for contagious diseases, also could be erected on the property. The opinion was expressed that possession could be acquired for \$500,000 or less, and that the total cost of construction would be about \$3,000,000.

St. Joseph's Hospital Residents.—The following are the successful applicants for internships at St. Joseph's Hospital: Drs. Foulkrod, Rigel, Homer Rhode, Mervin R. Taylor and Lamott.

Unclaimed Bodies.—The distribution of unclaimed corpses to the various medical colleges for dissecting purposes has produced friction between the State Anatomical Board and the pathological section of the Medical Board of the Philadelphia Hospital, which claims that mutilated bodies have been given to the colleges.

The Medical Class of 1881 of the University of Pennsylvania.—The Medical Class of 1881 of the University of Pennsylvania celebrated its twentieth anniversary with a dinner at the Hotel Bellevue on Wednesday evening, June 12, 1901. At the conclusion of the banquet a permanent organization was established with the following officers: President, Dr. G. E. de Schweinitz; vice-president, Dr. W. Easterly Ashton, secretary and treasurer, Dr. Daniel W. Nead.

Vital Statistics of Philadelphia for the week ending June 22, 1901:

Total mortality	410	Deaths.

Cases. Deaths.

84

NEW YORK.

Money for Long Island College Hospital.—George Foster Peabody and his brothers have agreed to contribute \$50,000 for the building and furnishing of an operating-room, as a memorial to the late Dr. A. J. C. Skene, for the Long Island College Hospital, which is to be practically rebuilt.

Manhattan Dermatological Society.—A regular monthly meeting was held on Friday evening, June 7th, 1901, at the residence of Dr. B. F. Ochs, No. 120 W. 120th street, with Dr. Wm. S. Gottheil in the chair. Dr. R. Abrahams presented a child of seven months with a **nevus of the left side of the nose near the inner canthus**. Electrolysis was advised for treatment. Dr. Geyser recommended the use of the positive galvanic current with a gold or platinum needle; the needle is to be inserted to the depth of 3 or 4 lines and the strength of the current to be $1\frac{1}{2}$ to 2 milliamperes. Dr. Bleiman advises radical surgical measures. Dr. E. L. Cocks prefers the negative galvanic needle. Dr. J. Sobel remarked that electrolysis would benefit the superficial vessels, but that there was a boggy skin below which would be rather difficult to affect. Dr. Gottheil considered the case a very troublesome one on account of the deep seated venous dilatation. Dr. J. Sobel presented two cases of **congenital ichthyosis** in a boy of 11 years and a girl of 3. Both were born with a soft, pliable skin and developed the ichthyosis three months after. Dr. B. F. Ochs presented a patient, a young woman of 25, in whom **psoriasis guttata** recurred every summer for ten years and disappeared spontaneously in the fall of the year. Dr. Gottheil reported a case of **psoriasis** in which the attacks improved and disappeared with rest in bed and a fluid diet. Drs. Oberndorfer, Cocks and Abrahams concurred in the diagnosis. Dr. A. Bleiman considered the case atypical.

Dr. J. Sobel presented a patient with a **seborrhoeal eczema** of the chest, back and abdomen, of three weeks duration. The eruption was red, scaly, with circinate patches at various parts. Dr. A. Bleiman remarked that while it was not a classical picture he would agree. Dr. R. Abrahams considered it herpes tonsurans maculosus et squamosus. He said that seborrhoeal eczema does not occur in rings. Dr. Gottheil would diagnose generalized ringworm and erythema multiforme. Dr. E. S. Cocks agreed with the diagnosis. Dr. B. F. Ochs inclined toward a diagnosis of herpes tonsurans, but admitted that there was seborrhoea with it. Dr. Oberndorfer remarked that the ring form does not speak against seborrhoeal eczema. He has seen many cases of annular seborrhoeal eczema, many cases with perfect rings. Dr. Gottheil presented a classical case of **acne necrotica** in a man of 45. Since childhood he has had lesions along the hair margins, temporal region and nasolabial fold. Patient has been treated by exposure to the arc light. All were agreed as to the diagnosis. Drs. Oberndorfer and Sobel spoke of the value of white precipitate ointment and of the danger of recurrences. Dr. R. Abrahams recommended iodide of potassium internally. Dr. Kruch through sulphide of calcium might benefit these cases. Dr. R. Abrahams presented a case of **lichen planus** in the declining stages. The lesions were situated on the dorsal surfaces of the hands and the extensor surfaces of wrist. Drs. Bleiman, Ochs and Oberndorfer remarked that at present diagnosis is difficult. Dr. J. Sobel said that at present the lesions were not indicative of any special condition. The extensor surface would seem to speak against lichen planus. Dr. Kinch would call it eczema. Dr. Gottheil states that in the retrogressive stage an eczema papule resembles that of lichen. Dr. Gottheil presented a case for diagnosis. The left hand presented a complete circle of papules progressing from the center. On the other hand there was staining and some old scar tissue. On the face there was a small papular elevation with sebaceous crusts. Dr. Kinch said it looks like a syphilide. Dr. R. Abrahams considers the face lupus erythematosus and the forearm herpes tonsurans. Dr. Oberndorfer would call it syphilis. Dr. A. Bleiman said that it looks like a tubercular process. Dr. Ochs considers it syphilis and Dr. Cocks lupus or syphilis. Dr. Sobel prefers to watch the case. Syphilis is

to be considered, but he inclines toward erythema multiforme. Dr. Gottheil said that the history and staining speak for erythema multiforme. Dr. B. F. Ochs presented a case of resolving syphilis of the papular, ulcerative type.

Medical Society of the State of New York.—Dr. Henry L. Elsner, President of the Medical Society of the State of New York, announces the appointment of his Business Committee for the ensuing year, consisting of Dr. Nathan Jacobson, Chairman, 430 S. Salina street, Syracuse; Dr. George Ryerson Fowler, 301 DeKalb avenue, Brooklyn; and Dr. William C. Krauss, 371 Delaware avenue, Buffalo. All letters and inquiries pertaining to papers and scientific communications for the semi-annual meeting to be held in New York City, October 15th and 16th, 1901, and the annual meeting, to be held in Albany, January, 1902, should be addressed to the chairman.

American Orthopedic Association.—At the meeting of the American Orthopedic Association held at Niagara Falls, May 11, 12 and 13, 1901, the following officers were elected: President, H. Augustus Wilson, M. D., Philadelphia; first vice-president, William J. Taylor, M. D., Philadelphia; second vice-president, G. G. Davis, M. D., Philadelphia; secretary, John Ridlon, M. D., Chicago; treasurer, E. G. Brackett, M. D., Boston. Philadelphia will be the place of the next meeting, to be held in May, 1902.

Influenza Spreading Among Horses.—Reports from veterinarians in New York are to the effect that influenza is spreading alarmingly among the horses in that city. At the New York Veterinary Hospital it was estimated that 12,000 or 15,000 had influenza, 5,000 of these being actually under treatment by doctors or their owners, while the remainder were not seriously enough affected to be disabled.

NEW ENGLAND.

Ten Thousand Dollars for New England Institutions.—The will of Essek A. Jillson, of Providence, divides \$10,000 among the Rhode Island Hospital, the Rhode Island Historical Society and the Home for Aged Women in Providence.

Maine Medical Association.—At the meeting of the Maine Medical Association held June 13, 1901, the following officers were elected: President, Dr. Frederick H. Gerrish, Portland; vice presidents, Dr. C. E. Philoon, of Auburn and Dr. J. M. Willis, of Guilford.

WESTERN STATES.

The Smallpox Status in Cleveland, Ohio.—It appears that Mayor Johnson, of Cleveland, Ohio, although he stated to the State Board of Health that he had personal objections to vaccination, nevertheless, is credited with the following statement to the Board of Health. "I have no thought of setting up my opinion against yours, and I desire that you decide just what measures shall be taken, and I assure you that all the money needed for carrying them out shall be forthcoming." It is now claimed that as Mr. Johnson has been Mayor of Cleveland for two and one-half months, while smallpox has been prevalent for three years, its prevalence is largely due to the lack of business ability and methods of the municipal authorities, and not to any attempt of the Mayor to put his personal opinions into practical effect.

West Chicago Medical Society.—The West Chicago Medical Society was organized a few days ago by a large number of west side physicians and the following officers were elected. Dr. E. D. St. Cyr, president; Dr. O. G. Wernicke, vice-president; Dr. G. M. Silverberg, treasurer; Dr. Gustavus Blech, secretary. Executive Council: Dr. A. M. Shabad, Dr. F. W. Henkel, Dr. J. M. Abello and Dr. S. Brownstein. The society will apply for affiliation with the American Medical Association.

College of Physicians and Surgeons Struck by Lightning.—During a heavy thunder storm on June 25, a bolt of lightning struck the College of Physicians and Surgeons, destroying the college building, which was one of the finest of its kind in the West. The rain was pouring heavily at the time, but, fortunately, there are so many hospitals and medical institutions in the neighborhood that it was necessary to remove the people only a short distance, most of them being taken to the County Hospital, one square distant. The College of Physicians and Surgeons is the Medical Department of the University of Il-

Illinois, situated at Champaign, Ill. The loss on building and equipment is practically total, and will approximate \$200,000.

Doctor George E. Ranney, of Lansing, Michigan, has been awarded a medal of honor by President McKinley for distinguished gallantry in the civil war. "On this occasion," according to the war department record of the action at Resaca, Georgia, May 14, 1864, "Assistant Surgeon Ranney, at great personal risk, went to the aid of a wounded soldier lying under heavy fire between the Union and Confederate lines, and with the aid of an orderly, carried him to a place of safety." On another battlefield the doctor was promoted to a brigade surgeon for bravery.

Dr. Joseph Eisen, of California, Attacked by Cancer.—Dr. Joseph Eisen, who has been doing considerable experimental work in endeavoring to discover the alleged microorganism of cancer, has been attacked by that disease himself. Dr. Eisen is of the opinion that he contracted the disease while performing his experiments. He has been operated upon and is recovering.

A Surgeon May Perform an Additional Operation Without Consent of the Patient.—According to a recent decision by Judge Kavanagh, of Chicago, a surgeon may perform an additional operation without the consent of the patient if he discovers a condition which renders such action necessary to preserve life after a first operation. The decision was rendered in the case of Mrs. Agnes Muehern against the Post Graduate Medical School and Hospital. Mrs. Muehern was operated upon by one of the professors of the college, and while she was under the influence of an anesthetic a condition as indicated was discovered and a second operation was performed. When the woman regained her health she brought suit against the college.

Meeting of the Chicago Pathological Society, June 10th, 1901. Dr. L. Hectoen, President.—Dr. Alice Hamilton presented a paper dealing with cell division in the central nervous system of the white rat before and after birth: the number and distribution of the mitoses, the period up to which they persist, and their character. Mitoses were found along the ventricular surfaces in the early stages of development, gradually ceasing here, and increasing in the outer layers, until at birth, almost all are in the outer layers. At birth mitoses are numerous and persist up to the end of the fourth day; beyond this period no examination was made. The dividing cells are of two kinds; 1st small, devoid of visible cell body, resembling cells of the neuroglia; 2nd, large, with abundant cytoplasm, round, pear-shaped or spindle-shaped. These are in the gray matter of the cord and brain and correspond in measurements with the multipolar and pyramidal cells.

Conclusion: In the later stages of development the offspring of the germinal cells become partially differentiated but without losing their powers to divide. The large dividing cells are, then, immature nerve cells; the small are cells of the neuroglia. In the case of the white rat, these cells retain their power of division until after the fourth day of extra-uterine life.

Wm. B. Wherry: A case of so-called malignant (staphylococcus) carbuncle of the upper lip followed by pyemia. A barber, twenty-three years old, entered Prof. Bevan's service in the Presbyterian Hospital on the 7th of February, 1901, and died on the 8th at 11.15 P. M.

About a week before his admission he extracted a "dead hair" from his upper lip. This was followed by redness of the lip and swelling, which rapidly extended to the side of the face and shoulder. He rapidly grew worse and died with all the characteristic symptoms of septic-pyemia.

The post mortem examination was held twelve hours after death by Prof. Hectoen. The anatomical diagnosis is as follows: Acute, diffuse, purulent and necrotic staphylococcus inflammation of the upper lip and adjacent parts of face; multiple abscesses and hemorrhagic pneumonic areas in lungs; double fibrino-purulent pleuritis; abscess in spleen; acute splenic swelling; cloudy swelling of kidneys and liver; persistent thymus.

Bacteriologically, a pure growth of the staphylococcus pyogenes aureus was isolated from the lip, heart's blood, pleural exudate, liver and spleen.

Histologically, the lip shows dense cellular infiltrations with foci of necrosis containing groups of cocci which stain by Gram's method. The lung contains many pneumonic and hemorrhagic areas and mycotic emboli. The other organs show the characteristic changes of a severe infectious process.

The dangers of this affection depend chiefly upon its location and the virulence of the infective agent; the prognosis is extremely grave on account of the liability to thrombosis and embolism.

The treatment of the early stage which has so far given the best results is excision of the necrotic area and packing with iodoform gauze. After thrombosis and embolism have occurred, treatment at the present time seems to be hopeless.

Wm. B. Wherry: The distribution of segmentation and fragmentation in the myocardium. Twenty hearts were carefully preserved and eighteen pieces were taken from each heart. In searching for changes, the divisions into simple segmentation, and degenerative fragmentation and segmentation, made by J. B. MacCallum, were kept in mind. Degenerative fragmentation and segmentation occurred twice in the left auricle. Segmentation was distributed in the following order of frequency: Left papillary muscles, wall of left ventricle, right papillary muscles, posterior surface of apex, etc.

The changes in the walls practically correspond to the changes in the papillary muscles.

"Diffuse" segmentation of both left papillary muscles accompanied by diastasis and displacement of the segments seems to indicate more or less general segmentation and fragmentation throughout the ventricles.

Dr. E. Friend: Cyst-adenoma of ovary. Patient thirty-two years old; married five years; never been pregnant; menstruation regular and painless; family history negative. About eight years ago severe pain developed in the region of the left ovary, but upon examination this was pronounced healthy. About one year ago a swelling appeared, extending from the symphysis pubis to the umbilicus, but this gave no pain until a month ago. She then entered the hospital and at operation there was removed from the right ovary a small, multilocular cyst. The patient made an uninterrupted recovery and was discharged from the hospital yesterday.

Adenomas develop as a result of disturbance in the formation of Pflüger's tubes in the growing ovary. Cyst-adenomas are simply adenomas which have undergone cystic degeneration; they consist of long, round, tortuous cavities separated from each other by connective tissue. These cavities may become obliterated entirely or partly by papilliform growths.

The present officers were re-elected for the coming year.

SOUTHERN STATES.

Dr. T. H. Hancock Elected.—Dr. T. H. Hancock, who for some time has been secretary of the association of Southern Railway Surgeons, has been elected president of that body.

Dr. Deering J. Roberts elected.—Dr. Roberts, a military surgeon during the Civil War and editor of the *Southern Practitioner*, Nashville, was recently elected president of the Tennessee State Medical Association.

A Mineral Survey of the State of Texas.—Ten thousand dollars was recently appropriated for a mineral survey of the State of Texas, to be conducted under the supervision of the regents of the University of Texas.

Richmond News.—Dr. E. Hill has been elected Demonstrator of Chemistry in the University College of Richmond, Va.

Old Dominion Hospital.—Ground has been broken for the magnificent new Old Dominion Hospital, at Richmond, Va. It will be ready for occupation in about 18 months.

MISCELLANY.

Army Medical School.—The following officers of the army have been detailed as members of the faculty of the Army Medical School, in addition to the present members: Col. William H. Forwood, assistant surgeon-general, vice-Col. Charles H. Alden, retired; Col. Calvin De Witt, assistant surgeon-general, as professor of military medicine; Major John Van R. Hoff, surgeon, as lecturer on the duties of medical officers in war and peace; Major William C. Borden, surgeon, as professor of military surgery, vice Col. Forwood, designated as President of the faculty; and Major Frederick P. Reynolds, surgeon, as instructor in hospital-corps drill and first aid to the wounded, vice Capt. C. D. DeShazo, who has been relieved.

Dallas Medical College.—Dallas Medical College, the Medical Department Trinity University, held its first exercises on June 18th, graduating eight in medicine and two in pharmacy. Acting-President Riley, of Trinity University, conferred the degrees.

OBITUARY.

Dr. W. C. Smith, at Linglestown, Pa., on June 16, aged 73 years.—Dr. M. Barton, at Alexandria, Va., on June 19.—Dr. R. L. Boggs, at Fairfield, Ill., on June 19, aged 91 years.—Dr. Erastus J. Buck, at Platteville, Wis., on June 20, aged 73 years.—Dr. Franklin H. Kerfoot, at Atlanta, Ga., on June 22.—Dr. Victor Popper, at San Francisco, Cal., on June 22.—Dr. John H. Groff, at Pennsgrove, N. J., on June 19.—Dr. Richard Lingle, at Orleans, Ind., on June 10, aged 63 years.—Dr. Edward Watson, at Grand Rapids, Mich., on June 17.—Dr. J. Henry McCarthy, at Birmingham, Ala., on June 12, aged 50 years.—Dr. William L. Worcester, at Danvers, Mass., on June 10, aged 56 years.—Dr. A. J. Baker, at Grafton, W. Va., on June 24, aged 40 years.—Dr. William Geiger, at Forest Grove, Ore., on June 16, aged 83 years.

Dr. W. Irving, at St. Mary's, Toronto, Canada, on June 19.—Dr. J. G. Jessup, at Berkeley, Cal., on June 19.

The Campaign Against Mosquitos.—It is stated that the sanitary department of Havana, in its campaign against mosquitos, proposes to plant eucalyptus trees in all the marshy and malarial districts in and around Havana, and a sum of £200 has been appropriated for that purpose and for the purchase of seeds. We are pleased to see a sanitary department that is really alive to the necessity for active measures against mosquitos, but we cannot help feeling somewhat doubtful of the wisdom of the particular measure which is to be adopted in Havana. In a paper by Professor Celli, which appeared in the *Journal of the Sanitary Institute* for January, that distinguished authority says that the eucalyptus, so far from being a protection against, is, like other trees, rather a shelter for mosquitos, and in the neighborhood of dwelling-houses adds to the danger of malaria infection. A different plan of campaign has been adopted in a New Jersey village called South Orange. The village Improvement Society proposes to attempt to get rid of the plague of mosquitos during the coming season, and has appointed a committee to instruct the inhabitants. The abandonment of rain barrels, the screening of water tanks in houses, and the placing of a thin layer of crude oil in cesspools and in pools of stagnant water which it is not possible to drain, will be advocated; and in order to enlighten the minds of the native population as to the importance of people safe-guarding themselves against mosquitos, Professor L. O. Howard, of the Department of Agriculture, Washington, who has made a special study of that branch of entomology, has been asked to deliver a free lecture on the subject.—*British Medical Journal*.

Sanitarium for Consumptives at Teneriffe.—A sanatorium for the open-air treatment of tuberculosis has recently been opened at Teneriffe. It is situated at an elevation of 1,200 feet above the sea level, and is surrounded by beautiful scenery. This is the first institution of the kind to be established on the island.

Rat Extermination.—The *Fort Wayne Medical Journal* states that one of the large manufacturing firms in Chicago is waging war upon rats by means of virus made under the direction of the Pasteur Vaccine Company. The virus is mixed with food and placed in the haunts of rats. It produces a fatal disease, which spreads rapidly and retains its virulence for some time. The virus is harmless to other species of animal life and has been tested officially in France and in this country, and in the United States Marine Hospital in San Francisco, where the results of the test were endorsed by the Chief of the Marine Hospital service at Washington. As rats are great carriers of contagion of all kinds, and are unusually destructive and annoying to the residents of our large cities, it is to be hoped that this new virus for the extermination of rats may come into use in all rat-infected districts.

Changes in the Medical Corps of the Navy, for Week ending June 22d, 1901.

ASSISTANT SURGEON H. M. TOLFREE, appointed assistant surgeon from June 14, 1901—June 17.
SURGEON C. F. STOKES, ordered to the Solace, upon arrival in the United States—June 18.
ASSISTANT SURGEON R. B. WILLIAMS, ordered to the Kearsarge, June 21—June 18.

ASSISTANT SURGEON F. M. FURLONG, detached from duty at Guam and ordered to the Solace for transportation home.—June 20.

ASSISTANT SURGEON R. K. McCLANAHAN, detached from the Culgoa and ordered to the Vicksburg.—June 20.

ASSISTANT SURGEON D. B. KERR, detached from the Vicksburg, and ordered to the Culgoa; to wait orders en route.—June 20.

Official List of the changes of the Changes of Station and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine Hospital Service for the 7 Days ended June 20, 1901.

C. T. PECKHAM, surgeon, granted extension of leave of absence on account of sickness, for thirty days, from June 20—June 19, 1901.

R. M. WOODWARD, surgeon, granted extension of leave of absence for 3 weeks from June 6—June 19, 1901.

C. H. GARDNER, passed assistant surgeon, granted leave of absence for 7 days from June 21—June 17, 1901.

G. M. CORPUT, assistant surgeon, relieved from duty at the port of St. Louis, Mo.—June 18, 1901.

Leave of absence for one month granted by Bureau telegram of May 16 amended so that said leave shall be for 21 days only—June 18, 1901.

DUNLOW MOORE, assistant surgeon, to proceed to Port Townsend, Wash., and assume temporary charge of service during absence of Passed Assistant Surgeon C. H. Gardner—June 17, 1901.

B. J. BROWN, JR., acting assistant surgeon, granted leave of absence for 14 days from June 20—June 17, 1901.

B. W. GOLDSBOROUGH, acting assistant surgeon, granted leave of absence for 2 days—June 20, 1901.

W. F. SCHLAAR, hospital steward, relieved from duty in the Hygienic Laboratory, and directed to proceed to Key West, Fla., and report to the medical officer in command for duty and assignment to quarters—June 19, 1901.

E. B. SCOTT, hospital steward, granted leave of absence for 12 days from June 24—June 19, 1901.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended June 22, 1901.

YELLOW FEVER IN HAVANA.

In his report of the vital statistics of Havana for the month of May, 1901, Major W. C. Gorgas, surgeon U. S. Army and Chief Sanitary Officer, states the following: "Our last case of yellow fever occurred May 7th. Since the first of March we have only had one death from yellow fever, which occurred March 13th. In no other year have the conditions, as to yellow fever, even approximated this. I cannot but hope that this exceptionally good condition is in great part due to the large amount of labor and money we are expending in the destruction of mosquitoes, and the circumstances of the case point in the same direction. The first time, April 21st and 22nd, we had two cases; and again, on May 6th and 7th, four cases. Each time the infected houses and three or four contiguous houses on every side of the infected house, were carefully gone over. Every room in each of these houses was closed and sealed, and insect powder burned in them at the rate of 1 pound to 1000 cubic feet. All standing water was drained away, where possible, and oiled where it could not be drained. The results look as if the focus of infection, at that particular point, had been eradicated. In the case of the patient taken sick March 8th after our disinfection, we went 42 days until the next case. Then an outbreak occurred April 21st and 22nd. We again disinfected, and have gone 24 days without a case. I am more particularly impressed by these figures, as we commenced our systematic destruction about the middle of February. Formerly we paid no particular attention to the mosquito, merely disinfecting for yellow fever as we do for other infectious diseases. The only part of the process that killed the mosquito was the formaline used in one or two infected rooms."

GREAT BRITAIN.

A New Kind of Sulphur Bath.—Harrogate, in Yorkshire, England, has a novelty in the way of a sulphur bath. Briefly described, by the application of electricity in a sulphur bath a man is converted into a "sulphur-coated" being. In other words, the electricity, acting upon the sulphur latent in the water, deposits the latter upon the skin of the patient in much the same way as electrolysis covers metallic goods with a plating of gold or silver. This process, according to the local practitioner, whose experiments have led to its discovery, is much superior to the ordinary sulphur bath in certain skin affections. The benefit, he says, is both greater and more rapid, for he finds that the deposit of sulphur actually placed upon the skin by electric influence is much more effective and curative than that nascent in the water. It is, in fact, driven into the skin, and thus keeps up the curative action until the next bath. The physician's experience with some of his patients is cited to support his theory, and the report of a chemist is added to show that an electric current passed through water will liberate sulphur at the positive pole by indirect electrolysis

of the sulphides and of the dissolved sulphuretted hydrogen, and so lead to the deposit of sulphur upon the skin. Is not this method of treatment worthy of investigation by physicians who make a specialty of skin diseases? At any rate, the accuracy of the above-named facts could be determined.—*Interstate Medical Journal.*

The Victoria Cross.—*The London Gazette* of June 5th contained the following, dated War Office June 4th:—The King has been graciously pleased to signify his intention to confer the decoration of the Victoria Cross for conspicuous bravery in South Africa on Captain N. R. Huse, New South Wales Medical Staff Corps, who, during the action at Vredfort on July 24th, 1900, went under a heavy cross fire and picked up a wounded man and carried him to a place of shelter.

Special Excursion to London and Paris.—An excursion to London and Paris in connection with the Tuberculosis Congress, July 23-26, and the British Medical Association, at Cheltenham, which meets July 26 to August 2, 1901 has been mentioned with special rates. The trip has been carefully designed in the interests of medical men who desire to attend the two great medical meetings this summer in Great Britain.

CONTINENTAL EUROPE.

A Woman Appointed Lecturer in Anatomy.—A young Italian woman, Dr. Rina Monti, who has published several scientific papers and who gained a university gold medal, has been accepted by the University of Pavia as a lecturer in anatomy.

Dr. Fedor Krause, Professor of Surgery at Halle, has been appointed Extraordinary Professor of Surgery at the University of Berlin.

Dr. Alexander Westphal, of Berlin, has been appointed Extraordinary Professor of Psychiatry at the University of Greifswald.

At the University of Munich the following Extraordinary Professors have just been appointed: **Dr. Siegfried Mollier**, in Anatomy; **Dr. Max Cremer**, in Physiology; and **Dr. Rudolf Haug**, in Otology.

Dr. Otto von Franke has been appointed Extraordinary Professor of Obstetrics and Gynecology at the University of Würzburg.

Dr. E. Graser, Professor of Surgery at Erlangen, has been appointed Professor of Surgery at the University of Rostock.

A Case of Duodenal Ulcer Associated with Primary Cancer of the Tail of the Pancreas.—B. P. Rutshinski and F. Ia. Tshistovitch (*Bolnitchnaia Gazeta Botkina*, Vol. XII, Nos. 13-14) report the case of a man, 53 years old, who presented on admission to the hospital symptoms pointing to duodenal ulcer. The man had vomited twice masses resembling coffee-ground, but there were no other evidences of cancer. Moreover, in the course of the first 43 days the patient gained 26 pounds, and was free from pain. The favorable course of the disease was interrupted abruptly by a peritonitis which terminated fatally within 3 days. The autopsy disclosed a perforated duodenal ulcer and a primary cylindrical carcinoma of the tail of the pancreas. The tumor was cystic and encapsulated, a condition which, the authors believe, explains the fact that the growth did not spread. The urine and feces examined during life showed nothing abnormal; the vomit contained free hydrochloric acid in considerable proportion. [A. R.]

Herpes Zoster.—Herpes zoster may be of central origin, either primary and infectious, or symptomatic of a medullary lesion; or it may be of peripheral origin, situated in the territory of the injured nerves. It is in the latter division that the traumatic cases of herpes zoster belong. Professor Gaucher made these remarks at a recent meeting of the Medical Society of the Paris Hospitals (*Bulletin et Mémoires de la Société Médicale des Hôpitaux de Paris*, 1901, No. 7), where he reported three cases. One was a man of 46, who, after being struck upon the cheek, developed marked herpes zoster, with headache. The second case occurred in a child of three, who injured the left side of his face. The third was a man in whom, after an injury to his left side, typical shingles appeared. All three cases speedily recovered [M. O.]

Society Reports.

A Correction.—Dr. Osborne's paper on "Medical Shock," read before the American Medical Association, was printed "Mental Shock" by an error of the reporter.

AMERICAN MEDICAL ASSOCIATION.

Section on Physiology and Dietetics.

FIRST DAY, JUNE 4, 1901.

The meeting was called to order by Dr. Winfield S. Hall of Chicago. A short executive session was held in which was considered the feasibility of fusing the Section on Pathology and Bacteriology and that on Physiology and Dietetics. Subsequent conferences resulted in this fusion to take effect in 1902. A joint exhibit will also be given.

Dr. Charles M. Hazen of the Medical College of Virginia, and Dr. R. Harvey Cook of Oxford, Ohio, were appointed to fill vacancies on the Executive Committee. The Section then adjourned to the following day.

SECOND DAY, JUNE 5, 1901.

The meeting opened at 2 P. M. with Dr. Charles M. Hazen of the Medical College of Virginia in the Chair.

Dr. Winfield S. Hall of Chicago read a paper on **The Evaluation of Anthropometric Data**. It was stated that the collection of anthropological data is almost universal in the practice of medical men. In the case of special lines of work this data is of fundamental importance. Anthropological data have potential, but no practical value as such; only through some process of evaluation can the potential value be made practical and form a basis for general conclusions. That method of evaluation which involves the use of the anthropometric average is both time wasting and inaccurate while one hour method based upon Quetelet's median value is accurate and is quickly and easily obtained. The median value is the value represented by the middle measurement of a series of measurements, i. e., that measurement which has as many values above it as below it. The median value is within the median group.

Dr. John Madden of Milwaukee supposed the purpose of the measurement to be the securing of a definite mean in measure, weight and general condition of a normal healthy child of a certain age. By this a boy could be measured as with a rule and square. Something of this sort should be on the books of the school, that from the child's entrance to his going out, his condition could be ascertained and any trouble traced to its cause. Dr. H. S. Drayton of New York thought this modern method as stated by Dr. Hall demonstrated very definitely the crudity of the old methods of anthropologists and ethnologists and proved their statistical value to be nil. Dr. Hall said in closing that the whole object of the method was the application of it by men collecting large masses of data for statistical tables. Though considerable data had been obtained, there had not yet been enough real accurate and scientific grouping done.

Dr. John Madden of Milwaukee read a paper on **The Education of the Degenerate**. A Physicobiologic Study. The paper as read was a synopsis of a chapter of a monograph and dealt with "What is the Remedy?" The entire paper was a plea for physical exercises to receive the same attention as mental training, and in certain cases it is a means of education where all other fail. Nerve cells develop by increasing dendritic branches and this takes place by physical as well as mental activity. Education of one group educates remote cells. Defectives were divided into three classes: (1) Those intellectually weak, but with self control; (2) Those who are bright but have not self control; and (3) those weak, and lack self control. Great benefit has resulted from physical training especially in those under number two. Physical education should be used in schools as normal children need it and defectives

can thus be reached when all else may fail. To curtail the production of defectives by mutilation or laws seems impossible. Attention should therefore be directed to environment, the well spring of vicious humanity. Alcoholism was stated to be the most frequent hereditary taint. Other taints frequently skip a generation, but it is not so with alcohol. The fight against degeneracy is a fight against alcohol. When faulty development is such as to warrant, the child should not be taught with normal children, but in a suitable institution. The paper dealt with those affected in a minor degree. The school should be "a brain condition house," and detestable studies should not be forced on the child. The plea is made not "to make a poor lawyer out of what could have been a good farmer." There should be small schools, and the individuality of the pupils should be known. Education is not merely the imprinting of ideas on brain cells; it is a biologic process with cell development and increase of dendritic fibres. Man is born with millions of cells which never become educated. Some are born with deficient cell development, and these are to be brought to as nearly normal condition as possible by physical and mental training. Dr. Winfield S. Hall of Chicago in discussion emphasized the necessity of physical development in the development of the mental, and referred to the influence of heredity on degenerates; especially was this marked in alcoholism. Dr. H. S. Drayton of New York City thought the term "degeneracy" covered a broad margin. Biological experiment had shown that but few of these degenerates were incapable of improvement. He related an instance of one, without sense or sensibility complete in which marked improvement had been obtained by the persistent endeavor of an assistant in the Institution for the Blind near Boston. Dr. Joseph Putney of West Virginia from his observations believed alcoholism a ruling factor in the cause of degeneracy. Dr. Madden in closing said he thought we were nearer to the appreciation of the actuality of an education when we stated that it consists in developing the nerve cell, giving to it an axis cylinder and some dendrites; the more dendrites, the better the education, that is, from a biologic standpoint. The word, degeneracy, he thought was much over-worked. A degenerate, he said, is something indefinable; generally a person of bad nutrition and one who does not recognize, and does not act in harmony with his environment.

Dr. H. S. Drayton of New York City read a paper on **The Nervous Relation in Diseases of the Nutritive System**. In this paper reference was made to social habits, methods of business, irregularities, excess of diet and nerve excitability as etiological factors in the causation of our national dyscrasia—dyspepsia. A brief consideration of the trend of opinion with a large class of pathologists concerning the treatment of gastric disorders was given. In the zeal to provide aids and substitutes for digestion the proper value and capacity of natural function seems to be overlooked. We limit the power and quality of the nervous apparatus having relation to gastric function and need to be reminded that nature has endowed it with a very broad field of adaptation to food stuffs. The author believes that the usefulness of the various ferments, etc., in gastric disorders is a limited one. The bio-chemistry of the human body is quite another thing from the best type. The nervous relation of alimentation, the vital sources of gastric metamorphosis is not sufficiently considered. That nature has reserves should also be remembered. That the nervous apparatus of the stomach must play a large part in the diabetic expression seems clearly made out by the exhibition of iodine. The neglect of the nerve function has been responsible for treating dyspeptic cases unnecessarily or contributing to greater disturbances of the alimentary organism by the administration of excitants and stimulants when that which was most required was rest. Nature in the recesses of sub-conscious activity can better manage the procedure of tissue building and repair than can be accomplished with tonics, emulsions and extractives.

Dr. Winfield S. Hall of Chicago believed the recommen-

dations of Dr. Drayton to be in line with a general movement in the medical profession—a less degree of medical interference, and the greater chance accorded Nature. Dr. Drayton referred in closing to the fact that among the old men of this country we would find the majority belonging to that class indifferent to the quality and quantity of their food, and certainly indifferent to the scientific relation of the food.

A paper on *Isolation of the Active Principles of the Suprarenal Gland. A Review of the Work by Dr. T. B. Aldrich of Detroit* was read by Dr. Houghton of the same city.

THIRD DAY, JUNE 6, 1901.

Food products from Diseased Animals was the title of a paper by Dr. D. E. Salmon of Washington, D. C.

In this paper it was stated that the question, what effect may the food products from diseased animals have in disturbing the digestion and in causing more serious disease in the human consumer, is one easily asked and dismissed by many with the same facility. Too little consideration is given to the millions of cattle and sheep and the greater number of swine and birds consumed each year. The Federal meat inspection service has been by many misunderstood and misrepresented. It is a sanitary inspection rather than a commercial inspection. The great difficulty in meat inspection is where to draw the line between meat that shall be classed as fit for food and that which shall be condemned. There is great need for the inspector being selected for his knowledge of pathology rather than his efficiency in politics. The desirability that the shipment of animals advanced in pregnancy for slaughter should be discouraged was urged. It was stated that the inspectors of the Bureau of Animal Industry are instructed to condemn all animals which are within two weeks of the time of parturition. Mention was made of certain animal parasites capable of infesting man and causing slight illness or serious disease. Reference was also made to inflammations of all organs and various infectious diseases accompanied by fever, emaciation and organic changes which affect the quality and wholesomeness of the flesh. Unquestionably the products of many badly diseased animals get upon the market and are eaten. What proportion of the cases of diarrhea, cholera morbus, etc., are due to such food? What is the extent of the danger from taking large quantities of tubercle bacilli in either rare meat or in uncooked milk, were dietetic questions which it appeared to the author might well receive more attention. More efforts should be put forth to secure a pure food supply. Those who are working in this direction need the encouragement and aid of the general practitioner of medicine and of the whole profession.

Dr. Winfield S. Hall of Chicago thought the paper opened an exceedingly wide field for research. He asked to what extent the experiments had been carried in the Washington laboratories and how far, in the opinion of the author, could tuberculous milk be taken with impunity. Dr. Paulson of Chicago testified to the good work done in the Washington laboratories, and deplored the successful effort in the small slaughter houses to avoid the beef inspection.

Dr. R. Harvey Cook of Oxford asked, why, other than from an esthetic idea, an animal before parturition is not so good for food. Dr. Salmon in closing regretted that there were many questions in connection with the subject he was unable to answer, and especially with regard to the effect of exhaustion and fright on the flesh of the animal. The Federal law that animals in transportation should be unloaded every 28 hours for feed, water and rest was openly violated. He had seen cases in which the animals in hot weather had been kept in stock cars for 96 hours. Consumption of meat shipped in this way he believed must have a considerable effect upon the health of the individual. He believed firmly in the danger of milk from a tuberculous cow. Experiments have shown that a considerable proportion of tuberculous cows give in-

fectious milk even with apparently healthy udders. In regard to the effect of the physiological changes in the last stages of gestation, he believed that the waste products from a fetus which are thrown into the circulation of the mother have a certain effect upon the flesh of the animal. The effect must be as marked as that upon the composition of the milk. There were as yet, however, but little data showing the effect of the meat upon the consumer.

A paper on "*Living on Bread*" Alexander Haig, M. A. and M. D. Oxon, F. R. C. P., London, England, was read by Dr. Harvey Cook.

The author stated that there are several forms of the Uric Acid Free Diet such as that which consists of milk, cheese, potatoes and fruit, and contains no bread, that which contains these things with more or less bread and bread stuffs, and, lastly, the form in which bread and bread stuffs form the chief sources of nourishment and a small quantity of fruit and vegetable are taken merely as sauces for the bread. In comparison were given the approximate quantities required in each of these diets for a man of 140 lbs. weight who is supposed to be young and leading an active life, therefore requiring a rather full diet, one that will yield 3.3 grs. of urea per lb. of body weight per day. It had long appeared to the author that bread which is preeminently the food of man is deserving of study and attention. Unfortunate results are obtained by taking uric acid containing foods on one hand, and trying with the other to wash out its excess on the other by copious libations of fluid far in excess of thirst. The great advantage of the bread diet in certain conditions of dyspepsia and especially in conditions of high blood pressure, is that it is a dry diet; that the fluid taken can be reduced to 1½ pints or even 1 pint in 24 hours till nature asks for more by making the patient thirsty; and, then alone can we be sure that we are not giving too much. The great point in the taking of bread stuffs and that which prevents them from causing dyspepsia is their thorough complete mixing with the saliva in the mouth. One other advantage of bread stuffs is their relatively slow digestion and metabolism, in virtue of which they give a steady supply of force and urea over a number of hours, this accounting at least in part for the great powers of endurance shown by the animals that live on them. Those who get their albumens from milk are in the position of a motor supplied with a quick burning oil which gives out great force for the first two hours but is sooner at the end of its resources; while those who get albumens from bread-stuffs cannot produce so much force in the first two hours, but will be able to go on longer. Bread stuffs form a very convenient diet and can be carried in the form of grain, meal, rice, macaroni or biscuits. Among the flesh-eaters disease and death are rampant, the natural term of human life is but rarely attained. Let anyone examine how many meat-eaters and tea drinkers between the ages of 17 and 23 have normal blood; how many from the age of forty-five have normal blood or normal circulation and do not suffer either from dyspepsia, depression and insomnia (not to mention Bright's disease and diabetes), or from arthritis, lumbago, sciatica, bronchitis. Dr. Winfield S. Hall in discussion believed a study of the literature of the influence of the metabolism of nitrogenous food showed the custom of taking too much of this food. He had read the greater part of Dr. Haig's writings and was in general, in accord with his statements. One or two apparently antagonistic points brought out in the paper he believed Dr. Haig could explain were he present. Dr. Paulson of Chicago thought the medical profession gave far too little attention to dietetics. He related an experiment he had made to determine the necessary amount of bread per day consumed in a bread diet. In a class of ten graduates on 16 ozs. of bread a day, as water dry as could be produced, a gain in weight was made by every one, some as much as three pounds in two weeks. Another experiment with a diet consisting of starch 16 ozs., nitrogenous food 2½ ozs. and of fat 1½

ozs. proved that the figures set down by Pettenkofer was entirely too great in this country and that normally we use a larger amount of carbonaceous food that is generally thought. The tendency is to overstock the system with nutrients which produce uric acid diathesis. Though not agreeing with all that Dr. Haig says, he considered the medical profession greatly indebted to him. Regarding the powers of endurance of persons living on a uric acid free diet, he stated that a number of the most successful long distance runners live upon an entirely non-flesh diet.

Dr. Joseph Putney of West Virginia called attention to the two classes of uric acid cases—those of dietetic origin, and those of tissue destruction origin. Nothing he thought was better recognized to-day than the fact of the breaking down of the leukocytes attended with the development of uric acid. This indicates the distinction between those cases of disorders of nitrogenous metabolism traceable to the short cut which the nitrogenous elements of food in excess take, and the long course which the nitrogenous metabolism of tissues involves. A vote was taken to send Dr. Haig an expression of the thanks of the Section for his paper.

Dr. R. O. Beard of Minneapolis read a paper upon **The Teaching of Practical Dietetics in Medical Schools**. In this paper was urged the advisability and necessity of including in the medical curriculum a course of instruction in practical dietetics. Reference was made to the establishment and successful working of the dietetic laboratory in the Harvard Medical School.

Dr. Winfield S. Hall of Chicago stated that he had seen the laboratory referred to by Dr. Beard and could testify to its thorough and beautiful equipment. Its establishment he believed marked an epoch in therapeutics. The fourth year in the medical school in his opinion was the place for it, and he felt that hospital internes should be held responsible for qualification in such instruction. Dr. Paulson of Chicago deplored the fact that the text-books contributed such scant instruction on dietetics, a subject upon which so much depended. Dr. Stewart of Michigan thought the paper of Dr. Beard very timely, and that the profession should have recognized long ago their duty in being able to tell their patients, how, when, and what to eat. "To be careful about your diet" is not intelligent instruction to a sick person. He stated that there was another school in which practical dietetics were taught, the American Medical Missionary College of Chicago at Battle Creek. In this school the teaching extends throughout the entire course. Dr. Beard in closing the discussion stated that acknowledgement of the success of dietetic work in Boston was due to Mrs. Ellen H. Richards of the Massachusetts Institute of Technology. It was largely under her suggestion that the course of dietetics at the Harvard University had been developed. He gave several interesting instances regarding the results of such work occurring in his own practice.

A paper on **The Pontobular Heat Center**, by Edward T. Reichert, M. D., of Philadelphia, was read by the Secretary. Professor Reichert said that although our knowledge of the thermogenic mechanism is still in a formative state, we nevertheless have sufficient experimental data to warrant the conclusion that in the higher animals the heat formed arises in part as a product incident to the activities of all forms of vital processes, and in part as a specific product of specific heat producing structures. The results of Rubner's researches leave no doubt as to the skeletal muscles possessing besides their motorial properties a specific thermogenic function, and as a consequence, that these structures besides producing heat as an incident to repair, growth and motor activity, also give rise to it as a specific product. They further show that the quantity of heat which arises by virtue of this special functions bears a reciprocal relationship to the amount formed as an incident to the activities of the body-structures generally, increasing or decreasing in adjustment to the variations in thermogenesis caused by rest and activity, etc., and

to the alterations in thermolysis which are dependent upon ever-changing internal and external conditions, so that as the output of heat incidentally produced increases or decreases, the quantity resulting from the specific thermal function of the skeletal muscles varies cooperatively in supplying the number of heat units required by the organism at any given time. Moreover, there can be no doubt that this specific thermal function is directly controlled by specific thermogenic centers which are located in the cerebro-spinal axis, although very little is known of their exact positions, functional relations and characteristics. A number of conclusions are drawn from the researches of many investigators.

Dr. Beard referring to Dr. Reichert's conclusions suggested as a possible source of error arising from the stimulation incident to section of afferent as well as efferent fibres related to the thermotaxic centres. The fillet from the ascending lateral tract of Gowers, which is believed to carry impressions of temperature to these centres, passing upward through the bulb and pons, might easily be involved in Dr. Reichert's pontine and bulbar sections, while lying in the lateral fillet, beyond the pons, it might escape in section of the crura. Adjourned.

AMERICAN NEUROLOGICAL SOCIETY.

Morning Session.

WEDNESDAY, JUNE 19th, 1901.

(From Our Special Correspondent).

The first paper presented after the address of the president, Dr. George L. Walton, of Boston, described an interesting case of myeloma of the spinal column by Dr. Thomas, of Boston. In the course of this Dr. Thomas discussed the value of albumosuria as a symptom of bone disease, and was inclined to attach considerable value to it. Although disassociation of sensation existed, a diagnosis of extramedullary growth was made and an operation was performed, with the result of relieving the paraplegia. The after-treatment has consisted of the administration of bone marrow and Coley's serum, and the patient is still doing well. In the discussion Putnam mentioned a case of sarcoma of the vertebrae benefited by operation, and another in which pain in the back had been the chief symptom, and which had also been improved by operation. Thomas in closing called attention to the microscopical preparations on exhibition. Spiller and Cohen reported a case of cervical and bulbar tubes. The symptoms commenced in 1872 with incontinence of urine, and distinct eye symptoms were noted in 1877. Later there was difficulty in deglutition, atrophy of the tongue, disassociation of sensation, Argyll-Robertson pupils and severe pains in the abdomen. The knee jerks persisted, and ataxia did not develop. At the necropsy the upper posterior roots and the column of Burdach in the cervical region were degenerated. The column of Burdach in the cervical region. There was also degeneration of some of the cranial nerves and of the oculo motor nuclei. The changes were atypical. Among the interesting special features were the springing mydriasis and the very slow course. Very few cases of this condition have been recorded. In the discussion Mills stated that he had seen the case in 1889 and had then suspected syringomyelia. He had seen five or ten cases of high tabes characterized by paresis of the eye and facial muscles, and disassociation of sensation on the trunk, and sometimes by symptoms of lumbar involvement. He suggested the term cervicobulbar tabes. Thomas, of Baltimore, inquired regarding the frequency of disturbances of speech in these cases. Jacoby stated that his clinical experience does not indicate that these cases are very rare, and mentioned two cases. Collins observes about 5 cases in 100 of this type. In Dr. Spiller's case the syphilitic virus had affected both the motor and sensory nerve fibers, a very rare feature, resembling bulbar palsy. Sailer mentioned a case of this nature with typical eye symptoms, fulgurant pains and ataxia in the arms, loss of sexual power and difficult micturition. The patient suffered from frequent severe laryngeal crises. He inquired if these were more frequent in high tabes. In concluding Spiller stated that cervical tabes was probably not rare clinically. He did not know whether early involvement of the eighth nerve was a valuable sign, and doubted whether laryngeal

crises were more common in this variety. Dr. Collins, of New York, reported a very remarkable case. Some time after an attack of sore throat the patient observed atrophy of the interossei of the right hand, followed by weakness, the process then gradually extended to the other limbs. There was difficulty of micturition, loss of sexual power, intense formication, and spasms in the lower extremities. There was no spasticity and only quantitative alterations of the electrical reactions. There were no objective sensory disturbances. The course lasted $7\frac{1}{2}$ years. At the necropsy the muscles showed extensive degeneration, the nerves chronic interstitial neuritis, and the cord degeneration in the posterior columns. The cells of the anterior cornua and of the spinal ganglia were normal. Dr. Knapp, of Boston, exhibited a case with muscular atrophy in the arm and shoulders, analgesia in the shoulders and Argyll-Robertson pupils, also two brothers suffering from pseudohypertrophic muscular atrophy. Mills mentioned a case occurring in a man of 75 characterized by weakness and pain in the back, and later in both legs. There was dissociation of sensation upon the dorsal surfaces of both feet. The reflexes were exaggerated, and at the necropsy only degeneration of the peripheral nerves was found. Dercum suggested that there might be some relation between neurotabes and primary neuroitis atrophy. Jacoby suggested that Collins' case was really one of multiple neuritis, and therefore doubts if reactions of degeneration necessarily occur in chronic neuritis. Dana remarked that tabes may be superimposed upon progressive muscular atrophy, but the pathological changes in Collins' case do not accord with this view. Spiller regarded the case as one of combined systemic disease. Diller called attention to the fact that a powerful grasp may persist in progressive muscular dystrophy. Thomas, of Baltimore, mentioned a case of bilateral facial palsy that he regarded as really one of progressive muscular dystrophy. Dercum stated that he had reported a case of progressive muscular dystrophy commencing in the face. Knapp, of Boston, mentioned the case of a woman who had fallen upon the floor at birth, and had always had complete paralysis of the face. She was otherwise normal. Collins, in closing, said that he regarded the case as one of degeneration of both motor neuros commencing at the peripheral ends.

AFTERNOON SESSION.

Dercum and Spiller reported the case of a man who had had a right-sided hemianesthesia and right homonymous hemianopsia for seven years as a result of an attack of apoplexy. At the necropsy a cyst was found in the carrefour sensitif on the left side, not involving the thalamus nor the motor fibers of the internal capsule. Mills discussed the localization of sensory and motor functions in the cortex. He referred to his own book and to Schaeffer's physiology, and mentioned several points in favor of separating the two areas, laying especial stress upon astereognosis and several cases that have been reported. He does not believe that the Rolandic region is concerned in sensation. Dercum agreed that the areas were separate. Walton did not believe that definite conclusions should be drawn from single cases. The stereognostic sense is sometimes lost in pure Rolandic lesions. Knapp congratulated Dr. Mills upon his change of opinion. He does not believe that the evidence is sufficient to enable us to localize the center for stereognosis. Langdon mentioned a case of Jacksonian epilepsy upon which operation was performed. The arm center was involved, and after breaking up adhesions about it, astereognosis occurred and persisted for 10 days, during which time there was some weakness. Sinkler had a case of dural tumor extending into the Rolandic region without astereognosis. Burr insisted upon the obscurity of the whole subject, but he believes that the motor region does not receive sensory impressions. Stereognosis is a conception and not a sensation, and therefore must have a center. Dercum has observed astereognosis in three cases with parietal lesions. Diller has observed a case with astereognosis. Lloyd urged that the subject is at present insoluble. He believes in separate areas for motion and sensation, and in a center for the stereognostic sense. Collins believes that the motor and sensory areas are identical, but that they may involve the parietal lobe. He does not think that a center for the stereognostic sense has been proven. Patrick thought that more facts were needed. He reported a case in which there was a

superficial lesion of the Rolandic region with sensory disturbances. Dercum mentioned that astereognosis can occur in other conditions than parietal lesions. Sailer reported a case of locomotor ataxia with astereognosis in one arm. He thought that sufficient attention was not always given to the associated sensory disturbances. Hammond believed that there was probably a definite center posterior to the Rolandic region, but that lesions elsewhere could produce astereognosis. Dana held to the essential identity of the sensory and motor areas. Mills, in concluding, stated that the opinion regarding the separation of the two areas is gaining ground. Burr and McCarthy reported a case of acute multiple neuritis (alcoholic) with incontinence of urine and fever during life. At the necropsy the characteristic changes were found, and degeneration of the vesical plexus, of the pneumogastric and phrenic nerves. There was also degeneration of the anterior and posterior spinal roots, perivascular sclerosis in the cord and chromatolysis of the cells and changes in the Gasserian ganglia. Collins inquired if there had been anemia. Burr replied that the changes were not similar to those found in anemic cords. Patrick inquired if vesical symptoms were common in multiple neuritis. Fisher and Knapp replied that they were not.

THURSDAY, JUNE 24TH, MORNING SESSION.

Dr. Henry J. Stedman of Boston gave an elaborate report of a case of general paralysis in the course of which gangrene had occurred in the fingers of the right hand and in the toes. The first symptoms had been loss of the radial pulse. After operation the mental condition of the patient had improved. The arteries in the amputated parts were approximately normal. Dr. Hammond exhibited photographs of a case of general paralysis in which extensive sloughing of the sacrum, heels, trochanters and gluteal region had occurred. There were tabetic symptoms, but he regards the gangrene as the result of alterations in the cord, possibly of myelitic nature. Dr. Jacoby regarded the case of Dr. Stedman as exhibiting two manifestations of the action of the syphilitic virus, the general paresis, and the peripheral gangrene. Dr. Riggs mentioned a case of general paresis and symmetrical gangrene, but the patient had also Bright's disease. Spiller mentioned a case of general paresis in which gangrene of the hand had occurred. There were changes in the ulnar artery, and degeneration of the nerve trunks, possibly secondary. The central nervous system was normal. Dana stated that some of the manifestations of symmetrical gangrene resembled those of hemorrhagic rheumatism and were amenable to the same forms of treatment. Knapp saw a case of symmetrical gangrene in a child of 8 who had also otorrhea so that there was possibility of infection. Knapp stated that Raynaud's disease was not a morbid entity. Arterial changes played a large part in its production. In closing Stedman stated that he considered syphilis a large factor. Dr. Knapp exhibited a patient with muscular dystrophy involving the muscles of the face. He called attention to the fact that many of these patients were able to work when the disease was far advanced. Dr. Putnam and Dr. Williams reported three carefully studied cases of tumor of the corpus callosum, presenting various symptoms, some of which were due to the involvement of neighboring structures. They then gave a very thorough analysis of the literature of the subject. Dr. Sinkler reported four cases of brain tumor. The first, a neurotic individual, had had trouble for 8 or 9 years with the left arm, several years later there was a history of a severe injury to the head. There were later attacks of melancholia, spasticity on the left side, and optic neuritis. Astereognosis did not exist. A spindle cell sarcoma of the dura was removed from the right Rolandic region. The second had optic neuritis, hemianopsia and other symptoms, the result of a secondary carcinoma of the occipital lobe. The third case had complex symptoms as a result of two growths, one in the motor region and another at the base. The fourth, a man of 60, had lost sexual power for three years. He developed symptoms of dementia, increased re-

flexes, eroticism, etc. A large tumor was found in the right frontal region involving the corpus callosum and the left frontal lobe, and a small growth in the left occipital lobe. Dr. Leszynsky and Dr. Glass reported a case that had presented weakness and spasticity on the left side, slowly increasing for several years. A dural endothelioma pressing upon the arm and leg center of the right hemisphere was removed and the patient recovered with a slight residual hemiparesis. Dr. Hammond exhibited a case of a brain with a tumor that compressed the right half of the pons and the fifth nerve. Dr. Knapp exhibited a specimen of a large tumor of the brain. In the discussion of these cases Dr. Sachs called attention to the adaptability of the brain to pressure, not only the motor and sensory, but also the mental functions adapting themselves to the changed conditions. He mentioned a case with mental symptoms varying from dementia to normal, whilst the optic neuritis gradually progressed to blindness. Also a case of trigeminal pain due to pressure from a tumor in the parietal lobe, relieved by trephining. Knapp mentioned two cases with tumor of the corpus callosum and a third case, probably of this nature, now under observation. Lloyd mentioned a case of tumor of the corpus callosum invading the paracentral lobule that gave rise to lock spasm, the patient being unable to relax his grasp; this he regards as a symptom of cortical irritation. It is possible that slowly increasing tumor does not cause epileptic attacks. Diller suggested that operation upon cerebral tumors be done in two stages, and reported a case successfully treated in this manner. The trephining relieved the headache. Spiller had seen three operations upon dural tumors in which there was considerable hemorrhage, and also a case of probable cerebellar tumor in which the symptoms were relieved by trephining, although no tumor was found. Browning stated that trephining often gives only temporary relief, and the same result may be obtained by the administration of gelsemium. Mills believed that the chief symptoms of callosal tumors were due to the involvement of neighboring parts. He urged that all cerebral operations should be done rapidly. Jacoby agreed that speed was important. He had observed that operations upon dural tumors gave rise to considerable hemorrhage. Langdon mentioned four cases of cerebellar tumor improved by operation. He believes operation desirable if there is any chance at all, especially if there is optic neuritis. Sailer suggested that prophylactic gelatine injections might be of advantage in cerebral operations in which hemorrhage was expected. Sinkler urged speed in cerebral operations. Putnam also urged speed. Lumbar puncture was often valuable as a preliminary measure. He approved of the use of gelatine. Dr. Ayres exhibited a specimen of osteoplaque of the dura.

AFTERNOON SESSION.

Dr. Sailer reported a case of cerebellar tumor occurring in a child of three. Sometime after a severe fall the patient developed strabismus, impaired vision, staggering gait, lost reflexes and a pulsating tumor upon the occipital bone with thrill and murmur. A meningocele was suspected, but operation disproved its existence. The patient died and a tumor of the cerebellum was found. There was no sclerosis in the spinal cord. Gordonier reported a case of cerebellar tumor with staggering gait, nystagmus, headache, exaggerated reflexes. At the necropsy a tumor of the superior vermiform process was found involving the corpora quadregemina. The histological findings were very carefully reported. Knapp considered operation justifiable in cerebellar tumors. The knee jerks are usually exaggerated, their loss may be due to cord lesions. In a case of tumor of the frontal lobe, cerebellar symptoms had been present. Dercum stated that the knee jerks are variable in cerebellar tumors. Their loss is perhaps due to irritative, their return to destructive lesions. Browning mentioned a case with intermittent toxic contractions of the muscles of the neck. Fisher inquired regarding the situation of pain in cerebellar disease. Langdon mentioned a case in which

the headache had been frontal. In closing Sailer stated that cases had been reported in which the loss of knee jerks was unilateral. He quoted the views of Beesor. His own case had not complained of headache. Dr. Pierce Bailey read a paper on traumatic hysteria with the report of a number of cases and the effect of ligation upon their condition. He stated that he regarded hysteria as a form of delusional insanity. Dr. Langdon mentioned the case of a man who some years after an injury had developed astasia abasia. He had hemianesthesia transferable by hypnotism. Diller mentioned a case that presented symptom $4\frac{1}{2}$ years after settlement. These were cured by suggestion. He also mentioned other cases. Knapp urged that hearsay evidence was useless. He mentioned a case injured by foot-pads, that had shifting anesthesia and varying visual fields. Later he developed typical disseminated sclerosis. He regards the physical condition of the patient as more important than heredity. Herrick inquired to what extent Dr. Bailey employs the educational method. Riggs mentioned a case of traumatic hysteria with dementia. Bailey in closing said that it is very difficult to obtain subsequent histories in these cases and that we must depend upon the ability of the patient to work or not. Dr. Lloyd reported as a hypothetical case, the instance of a man employed to etch glass who developed the form of wrist drop characteristic of lead poisoning. There were none of the other symptoms. He had previously worked in lead, and the question arose whether hydrofluoric acid could have produced the condition. Courtney suggested that lead was liberated in the etching of glass. Knapp inquired if lead had been found in the urine. Lead does not always produce typical wrist drop, it may cause paralysis of the shoulder, foot drop and even of the whole arm. Lloyd, in closing, did not believe that enough lead was liberated in etching glass to cause poisoning. The supinators are rarely involved in lead paralysis. Hydrofluoric acid is purely corrosive. Dr. Dercum read a paper on the classification of insanity to which the unusual honor of an extension of the time limit was accorded. His classification is purely clinical and can perhaps be called a grouping; in brief it consists of five groups. 1st delirium, confusion and stupor; 2d, mania and melancholia, to which circular insanity may be added; 3d, paranoia; 4th, neuresthenic insanity; 5th, dementia. Lloyd admits that the present classification of insanity is unsatisfactory. He is not sure that mania and melancholia are closely associated, although both may occur in the same case. Many psychoses are degenerative in type, and he does not believe that the true psychoses should be so sharply separated from the degenerative insanities as Kraft Ebing suggests. Knapp believes that we should agree in methods of examination, and that the localization of the process is more important than its nature. Dementia is a terminal process as the results of an active process that interferes with the function of the neurons. He has observed systemic delusions unattended by delirium, produced by alcohol. Mills is not prepared to admit the close relationship of mania and melancholia. He regards Dercum's classification as useful. Fisher believes that no clinical classification can be satisfactory. Mania and melancholia differ clinically. Dercum in closing argued that a clinical classification was the simplest and clearest. Dementia is a clinical entity and must be classified. He does not believe that a poison can ever produce paranoia although alcohol may predispose to it.

Torticollis Treated by Suture of the Sterno-mastoid Tendon.—Dr. B. Sengenese reports two cases of torticollis in children, which were cured by open division of the mastoid tendon, after which a collar was applied. This was removed daily while movements of the head were practiced. In both cases permanent recovery resulted. Sengenese objects to subcutaneous tenotomy, thinking an incision large enough to see the tendon is necessary. This is sewed up at once and the collar applied. Movements of the head

1.—Edmund Owen discusses the anatomical associations of the kidney from a surgical standpoint, dealing first of all with the nerve associations of the kidney. Under this head is mentioned the association of pain in the testicle in cases of renal disease, which is accounted for by the fact that the testicle is developed in close association with and proximity to the kidney. The question of vomiting is mentioned, and its possible origin in a disturbance of the pneumogastric due to kidney infection. The vascular associations of the kidney are next described and the relation between the kidney and the peritoneum. In speaking of the associations of the kidney with the colon the author cites several instances in which a malignant disease of the colon has been improperly diagnosed as disease of the kidney. Because of the relationship between the stomach and the left kidney diseases of these organs have not infrequently been mistaken for one another. In speaking of rupture of the kidney the author thinks that nephrectomy should not be done unless absolutely necessary since the more conservative methods of treatment preserve the kidney. [J. H. G.]

2.—Treated editorially.

3.—Benjamin Duke reports a case of oblique fracture of the tibia and fibula, in which at the time of the accident and during the subsequent treatment of the case up to the 80th day only a fracture of the fibula was suspected. A skiagraph at this time, however, showed that there had also been an oblique fracture of the tibia, and that separation of the fragments was quite marked. The patient recovered with most excellent function of the part, being able to dance, play tennis, and walk great distances. The case illustrates the fact that X-ray pictures are no indication as to the subsequent outcome of cases of fracture.

[J. H. G.]

5.—T. E. Gordon reports a case of cervical rib in which there occurred obliteration of the arteries of the right arm with a resulting gangrene of a portion of several fingers, and in which excision of the rib was productive of great improvement. The author discusses at great length the question of obliteration of the blood vessels in its relation to pressure, and quotes extensively from the literature of the subject. The conclusions reached are as follows:

1. The cervical rib was in some way the cause of the arterial obliteration.

2. The circulation through the subclavian was not obstructed.

3. The occurrence of embolism may be excluded.

4. The manner of the obliteration suggests thrombosis, which in turn implies a preceding disease of the endothelium.

5. The cause of this arterial disease is very probably, in part, the carrying of heavy weights.

6. If the rib acted directly on the artery, it must have done so in some way upon which present pathology throws no light.

7. The rib may have acted indirectly on the artery through the nerves.

8. The nerves are more likely to have suffered than the artery, and nervous symptoms are much more common than circulatory.

9. A nerve lesion is capable of causing gangrene.

10. A nerve lesion may cause structural changes in the blood vessels.

11. The absence of clear signs of a peripheral neuritis is a striking argument against the theory of nerve origin.

12. The case resembles the local phenomena of Raynaud's disease, which is almost certainly a neurosis, and here there is commonly an absence of usual symptoms of neuritis.

13. In Raynaud's disease, however, the arteries are stated to be usually healthy.

14. From the occurrence of such changes in Raynaud's disease, we may conclude that not only from nerve lesions generally, but from disease of vasomotor nerves in particular, structural changes in arteries may arise.

15. In cases of cervical rib there occasionally occur symptoms which may possibly be explained by injury to the cervical sympathetic. Such are (1) increased heart action; (2) excessive subclavian pulsation, and sometimes fusiform dilatation of the artery; (3) abnormal sensitiveness of the arm affected to external cold; (4) thyroid enlargement.

A study of the anatomy of the region concerned suggests that the abnormal rib may have excited its evil effects not at its distal, but at its proximal extremity; here the rib is an intimate relation not only of the seventh and eighth cervical and first dorsal nerves, but also of the inferior cervical sympathetic ganglion and its branches. The number of these sympathetic connections is much greater with the lower than the upper brachial nerve trunks."

[J. H. G.]

6.—Andrew Clark reports a case of carcinoma of the breast too far advanced for operation in which the use of the X-ray for nine weeks produced a marked improvement. In this case the rays were applied for 15 minutes at a time for 5 days out of a week. The ulceration and discharge greatly diminished and the axillary glands became smaller and general improvement followed. [J. H. G.]

7.—A contribution by J. Herbert Parsons to the pathology of toxic amblyopias and a brief résumé of the researches that have been conducted since Samelsohn investigated the changes occurring in the papillo-macular bundles of the optic nerve in tobacco amblyopia.

[M. R. D.]

8.—Stewart reports the case of a man 30 years of age who presented to a marked degree nearly all the classical symptoms of the paralysis of the cervical sympathetic, and who presented to a marked degree nearly all the classical limits of anidrosis. The patient was a soldier who had been wounded in the left side of the neck by a Mauser bullet. The bullet entered 1½ inches below the mastoid process and came out through the seventh right interspace in the posterior axillary line. At the time of the injury he felt an "electric shock" all over his body, but especially in the right arm, which immediately became totally paralyzed. At the same time he suffered from hemoptysis, which persisted for 3 days, together with dysphagia. The patient's temperature became normal on the fourth day, and he was soon able to go about. The right arm gradually recovered its lost power so that it nearly, but not quite, reached the normal. Vision in the right eye was slightly impaired. The patient did not sweat on the right side of the face and neck, nor on his right upper extremity. There was no atrophy of any of the muscles. There was an area of slight analgesia, along the inner side of the whole right upper extremity to the fingers. On the dorsal surface, the anesthetic area extended quite to the outer border of the arm and forearm, and on the anterior surface it extended down the center of the limb, passing longitudinally through the ring finger, both on its palmar and dorsal surfaces. The right pupil was smaller than the left, as was also the right palpebral tissue. There was also slight enophthalmos on the right side. The lesion was evidently one which affected the entire right brachial plexus as well as the right sympathetic nerve. [J. M. S.]

8. Vitality After Severe Injury. W. H. CLAYTON GREENE.
8. The Morbid Anatomy and Origin of the Various Presystolic Murmurs Heard at the Apex. C. C. GIBBES.

2.—Christopher Heath makes retention of urine the subject of a clinical lecture. Reference is first made to retention occurring at birth from a tight prepuce. Later in life obstruction may occur in a child from impaction of a calculus. This is not infrequent and should always be thought of. Reference is also made to retention following a tight thread about the penis placed either by the child or the parent or the nurse to prevent nocturnal enuresis. A case is recalled in which gangrene of glands resulted from this cause. Gonorrheal retention may be due to an inflamed prostate. A digital examination of the rectum should always be made when retention occurs in the course of this disease. It must not be forgotten, however, that a prostatitis may result from other causes than from gonorrhea. Spasmodic retention occurs later in the course of gonorrhea, and is usually the result of excessive indulgence in alcohol. In retention from stricture after the condition has been relieved with the catheter it is well to leave the instrument fixed in the urethra. Where it is impossible to empty the bladder by means of a catheter aspiration above the pubes is recommended. The author asserts that it is a safe method of procedure if properly and aseptically done, and that unless too frequently repeated, is not apt to produce infection. Retention from anatomy of the bladder is next described. In this connection it must be always remembered that dribbling of urine indicates a distended bladder, and in such instances the bladder should always be emptied every 6 to 8 hours for several days and strychnia administered. Sometimes the electric current is of value in these cases. Retention from an enlarged prostate is finally mentioned, and the author calls attention to the fact that retention may occur from enlarged prostate after exposure to cold when before the enlarged gland had given rise to no trouble. The use of the catheter in these cases will nearly always bring away some blood, and it is well to prepare the patient for this before the instrument is passed. The hemorrhage in these cases is seldom serious. Occasionally, however, it may be found that the bladder is filled with large clots. In these cases great benefit will follow the administration of opium. Hysterical retention is mentioned, and the use of the catheter in these cases is to be avoided. The condition usually occurs in young females and is relieved by a hot bath or by suddenly throwing cold water over the head and shoulders. [J. H. G.]

3.—Gairdner gives an account of an early experience concerning the therapeutic virtues of potassium iodide in asthmatic affections. The author gives a detailed account of a case that was treated with the iodides with favorable results. [F. J. K.]

4.—Edington has contributed to medical literature a preliminary communication on an outbreak of rat plague at Cape Town. Upon the author's arrival at Cape Town he was informed by the Colonial Secretary that rats

were dying of bubonic plague. The author examined a rat that had died in one of the docks and isolated from this animal a bacillus with rounded ends, its size varying from 4 micromillimeters to 1.5 micromillimeters in length, and from 1.2 to 1 micromillimeters in breadth. This micro-organism did not show the well marked bipolar staining reaction which is so characteristic of the bacillus pestis. In the primary culture there was great morphological variation in the bacteria. Some of the micro-organisms were diplococci or diplobacteria, while others were somewhat spherical. This rat bacterium was found to be pathogenic to guinea pigs, the animals dying a few days after inoculation, but the micro-organism was not pathogenic to rabbits. Rabbits inoculated by this rat plague were not protected from bubonic plague when subsequently inoculated with the bacillus pestis. Pigeons were highly susceptible to the rat disease. The author concludes that there are marked differences between this rat disease and bubonic plague. [F. J. K.]

5.—Buzzard discusses alcohol and arsenic in the etiology of alcoholic neuritis, and concludes that clinical observation is responsible for alcoholic neuritis, and further, that in London alcoholic neuritis more often follows spirit-drinking than from other kinds of alcoholic beverages. [F. J. K.]

6.—Colbeck and Pritchard suggest an explanation for the vulnerability of the apices of the lung to tuberculosis. These authors conclude that alteration in the shape of the chest combined with misplacement and deficient musculature of the shoulder girdle are largely responsible for the susceptibility to tuberculosis. [F. J. K.]

7.—C. B. Keetley discusses the surgical treatment of ulcer of the stomach in which there occurs hemorrhage. The author differentiates between severe hemorrhage and slight hemorrhage, the danger of the former being immediate and remote and of the latter only remote. Four cases are reported. Case No. 1—Female, aged 20 years; a gastric ulcer adherent to the diaphragm and pancreas. The patient had had considerable hemorrhage, the last being nearly fatal. The ulcer was severed and sutured, the patient recovering. The pain returned and gastro-enterostomy was done, which cured the patient. Case No. 2—Female, aged 32, suffered from a severe gastric hemorrhage. In this case rest and opium and rectal feeding were employed; no operation was done and the patient died on the 12th day. Case No. 3—Woman, aged 39 years, had suffered from gastric trouble for a long time and had had numerous severe hemorrhages. In this case Loreta's operation was done, the pylorus being stretched to 4½ inches, internal circumference. This operation was followed by recovery. Case No. 4.—Was one which was not under the author's care. The patient was a man of 40 years of age who suffered from a duodenal ulcer which perforated the pancreaticoduodenal artery and produced death. No operation was done in this case. The author thinks that the bleeding vessels in the gastric wall should be tied, and that pressure alone should not be relied upon. The benefit following operation for gastric ulcer is discussed at some length, and particularly the question of keeping the stomach contents in an aseptic condition. It has been suggested that the good results following gastro-enterostomy are due to the fact that the bile and pancreatic secretion pass into the stomach in small quantities and produce there an aseptic effect. If there be any truth in this theory the author suggests the possibility of administering orally the secretions of the liver and the pancreas or the fresh glands themselves in the medical treatment of gastric ulcer. Attention is called to the very excellent results following the operative treatment of gastric ulcer, particularly when hemorrhage is present. [J. H. G.]

8.—W. H. Clayton Greene reports a case of a man who fell some distance and was impaled upon an iron railing. With stimulation the patient lived for 9 hours. At the post-mortem there was found a fracture of the sixth, seventh, eighth, ninth and tenth ribs, complete perforation of both walls of the stomach, perforation and laceration of the diaphragm, collapse of the left lung and perforation of the pericardium and of the left ventricle. [J. H. G.]

9.—Gibbes writes upon the morbid anatomy and the origin of the various presystolic murmurs heard at the apex. The author states that the presystolic murmurs heard at the apex cannot be regarded as pathognomic of mitral sounds. The presystolic murmur has been heard

during life under the following conditions: (1) mitral disease (stenosis); (2) a thrombus in the left auricle obstructing the mitral orifice; (3) dilatation of the mitral orifice without valvulitis, the heart being dilated and hypertrophied; (4) hypertrophy and dilatation of the ventricles without thickening and roughening of the mitral segments; (5) hypertrophy of the left ventricle with aortic insufficiency; (6) aortic stenosis with fusion of the aortic cusps, permitting regurgitation; (7) hypertrophy of the left ventricle from nephritis with slight thickening of the anterior mitral flap, and thickening of the chordae; (8) hypertrophy and dilatation of the right ventricle from atheroma of the pulmonary artery, with the right ventricle from atheroma of the pulmonary artery, with dilatation of the mitral orifice, and pericardial adhesions. The author emphasizes that the presystolic murmur cannot entirely arise from the auriculo-systolic blood-current. [F. J. K.]

MEDICAL RECORD.

June 22, 1901.

1. Hernia of the Urinary Bladder. W. S. CHEESMAN.
2. The Nauheim Treatment. H. NEWTON HEINEMAN.
3. Nephrorrhaphy with Flap Fixation. ARNOLD STRUMDORF.

1.—W. S. Cheesman reports a case of **hernia of the urinary bladder** and includes the discussion and review of 180 cases collected from the literature. The bibliography is especially valuable. The principal cause of bladder hernia is direct traction exercised through the peritoneal coat by the weight of the hernial mass, or by pull on the sac during ligation in operations for radical cure. In one-sixth of the cases symptoms occur sufficient to arouse suspicion, sometimes amounting to certainty of the existence of the abnormality. In about one-fourth of the cases, it may be possible during operation to recognize the bladder and avoid injuring it, and after one hernial sac has been found, any structure resembling a second should be regarded as bladder, until proved otherwise. When the bladder is wounded, the best procedure is immediate suture by two layers of catgut, and closure of the hernial wound by Bassini's method: a small drain only being left leading to the bladder suture line. The bladder wall, when thin, may be freely resected preparatory to closure. It is found that urinary fistula nearly always closes spontaneously. Injuries of the bladder have been directly responsible for death in only 10% of the hernia cases in which they occurred. [T. L. C.]

2.—H. N. Heineman, of New York, contributes a carefully prepared article on the **Nauheim treatment**. This paper is based upon the author's personal experience at Nauheim for two months for each year for ten successive years. The method of the treatment is given in detail. The factors in applying the baths which constitute an important element are: First. The warmth and the fact that it is a natural warmth, avoiding any injurious application of heat by which important elements are dissipated. Second. The presence of alkaline salts and of metals in large quantities, and of rarer elements whose exact value is uncertain. Third. The large quantity of carboic acid held in an active form and its coincident combination with salts and other elements. Finally. A certain quantity of electro-magnetism or magneto-electricity which these waters have in common with other springs. When patients with weak hearts are placed in a Nauheim bath of the usual temperature of $33\frac{1}{2}^{\circ}$ to 35° C., they first experience a feeling of oppression of the sternum, which is at times somewhat uncomfortable, but is never serious and soon passes off. The patient's pulse becomes slower and fuller in the bath and the respirations are likewise fuller and fewer in number. The bath promotes relaxation of the skin and dilation of arterioles and so relieves internal engorgement for the time being. It is not to be wondered at that in a certain number of cases in which the chest walls are so thin as to permit the mapping out of the exact size of the heart, we find the heart occupying a smaller area in some of its dimensions, at times in all, and evidently contracted as a result of the greater ease with which it drives the blood in consequence of the internal disengorgement. Heineman regards the bath treatment as an excellent nerve tonic, and believes that there is an important electric or magnetic influence. Tissue metabolism is remarkably affected. Rheumatic and gouty conditions are remarkably improved under this treatment. The exercises are a most important ad-

junct to the baths. General directions for the resistant exercises are given. The importance of proper diet is insisted upon. Alcohol being especially contraindicated as well as coffee. In arteriosclerosis the diet should be largely milk and not less than two or three liters daily should be taken. Starchy food is to be avoided. The Nauheim treatment is indicated for rheumatism and gout, inflammatory exudates, whether pleuritic, abdominal, or pelvic. In nervous disorders such as functional and incipient organic spinal disorders spinal congestion, neurasthenia, locomotor ataxia in its early stages, chorea, sciatica and certain forms of neuritis, circulatory disorders and cardiac disorders. It is contra-indicated in chronic Bright's disease, aneurysm in any advanced form as well as arteriosclerosis. A number of sphymographic tracings are given illustrating the changes in the pulse brought about by this treatment. [T. L. C.]

3.—Arnold Strumdorf reports a case of **nephrorrhaphy with flap fixation**. An incision was made obliquely downward and somewhat outward, extending from the lower border of the last rib at a point corresponding to the edge of the erector spinae group to the iliac crest and through to the perirenal fat. Incision of the fat capsule was made along the whole length of the kidney, the edges of the incised fat being drawn out of the wound as far as possible, and this redundant fat being ablated on both sides flush with the bottom of the wound. The kidney was pushed as near to the surface as possible, and steadied there by pressure exerted through the abdominal wall by the hand of an assistant. The capsula propria was incised longitudinally, exactly in the median line to within about three-fourths of an inch from either pole. A pair of closed, curved, blunt-pointed scissors was introduced beneath this capsular incision, and the capsule was carefully separated from the kidney substance for an area corresponding to the longitudinal capsular incision in length and to the lateral borders of the kidney in width. The free capsule was now raised by mouse-tooth forceps; two flaps were formed with blunt-pointed scissors by splitting the capsule laterally at each end of the longitudinal incision. The flaps were secured in the grasp of T-shaped forceps, while two silkworm retention sutures, equi-distant from each other and from either pole of the kidney, were passed through skin, superficial fat, the tendons of the abdominal muscles, the cut and trimmed edges of the perirenal fatty capsule, the fibrous capsular flaps, and the parenchyma of the kidney at a depth of about three-fourths of an inch from its surface, and left untied for the time being. The object of these sutures was not only to aid in relieving tension, but to obliterate any possible hollow spaces, thus obviating the necessity for drainage, and at the same time securing firm coaptation of broader surfaces for subsequent cicatricial union. Longitudinal slits, corresponding in location and length to the position and width of the fibrous capsular flaps, were next made through the adjacent muscular tissue, and the flaps drawn through these slits were secured in place by running suture of fine chromicized catgut. Three interrupted sutures of No. 3 chromicized gut were next passed so as to embrace muscle and kidney substance at a level with and equi-distant from the above-mentioned silkworm sutures, and tied. The final suture included skin, superficial fat, and fascia, after which the silkworm sutures, originally left hanging loose, were drawn taut by means of shot and plate. Primary union occurred, the removal of the silkworm sutures being effected on the eighth day. [T. L. C.]

NEW YORK MEDICAL JOURNAL.

June 22, 1901. Vol. LXXIII, No. 25.

1. Syphilitic Fever, with a Report of Three Cases. (From the Service of Professor William Osler). THOMAS B. FUTCHER.
2. The Evolution of the Ophthalmoscope, and What it has done for Medicine. SAMUEL THEOBALD.
3. An Introduction to the Psychological Study of Backward Children. WILLIAM B. NOYES.
4. Inguinal Bubo as a Complication of Malarial Fever. A. C. SMITH.

1.—Thomas B. Fletcher reports **three cases of syphilitic fever**, giving the various periods at which it may occur during the course of infection; (1) It may occur, in very rare instances, so long as three or four weeks before the onset of the secondary skin eruption. This early fever is

puzzling, and is likely to be attributed to some other cause until the eruption makes its appearance; (2) It may precede or be coincident with the appearance of the secondary eruption. This is the so-called "fever of invasion," and it is a very common and important symptom of secondary syphilis; (3) the fever may occur at any time during the course of the secondary or tertiary stages. The late occurrence of the fever is a most striking feature. It generally precedes the appearance of the secondary eruption by a week or ten days. Rarely does it antedate it by more than two weeks. The authorities now agree that this fever is a symptom of the invasion of the system by the organism believed to be the cause of syphilis or by its toxic products. At the onset of the fever there is often a transitory erythema of the skin which appears, to be followed by the true syphilitic roseola a few days later. The fever may be present in any of the following clinical types: (1) A mild continuous pyrexia, where the temperature ranges in the neighborhood of 101° F. Osler states that this type is not uncommon in the fever which ushers in the constitutional symptoms; (2) A remittent type of fever, with morning drops toward normal and evening exacerbations. This is considered the usual character of the fever of invasion; (3) A definite intermittent fever. This is the most remarkable form of all, and is the type which is most likely to lead to error in diagnosis. The author emphasizes the following points in connection with syphilitic fever: (1) In all cases of fever of obscure origin the possibility of its being syphilitic should be borne in mind; (2) Experience has shown that physicians of reputation, as well as those of limited experience, are prone to mistake the condition for one of the acute specific fevers; (3) The affections for which syphilitic fever is most often mistaken are malaria, typhoid fever, tuberculosis, sepsis, and occasionally rheumatic fever; (4) The fever may occur as early as four weeks previous to the appearance of secondary skin eruption, or, what is of greater importance, late in the disease after tertiary manifestations have existed probably for years; (5) The fever may be continuous, remittent, or intermittent. The remittent type is regarded as the most frequent form in the fever of invasion. The fever is often associated with chills and sweating. (6) Careful examination of the long bones and viscera for evidences of tertiary lues should be made in all cases of fever of obscure origin. [T. M. T.]

3.—William B. Noyes, in his article on an introduction to the psychological study of backward children gives the following points to be distinguished: (1) Those in whom the faculty of perception is deficient, including all those who have been born defective in their special senses. In extreme types, he states, are included the so-called idiots by deprivation, who are idiots because they lack certain special senses and power of perception, lack the power of attention, without which the most painstaking instruction is without result; (3) This class is characterized not by defect of special senses or the power of attention, but by defect or diseases of the will. [T. M. T.]

MEDICAL NEWS.

June 22, 1901. (Vol. LXXVIII, No. 25).

1. Psychic Epilepsy, with the Report of a Case. J. W. COURTNEY.
2. The Medical Expert Evidence in the Case of the Davis Bellevue Hospital Homicide. R. L. PRITCHARD.
3. Obstipation. STERLING B. TAYLOR.
4. A Study of Some Complications and Sequelæ of Typhoid Fever. H. A. HARE.

1.—J. W. Courtney defines **Psychic Epilepsy** as a peculiar pathological alteration of consciousness and memory which may precede, accompany, follow, or even according to certain observers, take the place of the epileptic fit. Pathophysiologically, such states of mind are regarded as the result of inhibitory or irritative explosions within that portion of the cerebral cortical territory which presides over psychic processes. Hence, simultaneous motor disturbances, the result of a synchronous inhibitory or irritative explosion primary within the motor cortical territory, are constantly lacking. Nevertheless, associated motor phenomena, sometimes of the most complicated and purposive types, do occur and to account for them properly we must consider them as end results of psychic processes. [T. M. T.]

3.—Sterling B. Taylor describes **obstipation** as an obstructive costiveness due to a stuffing or cramming against an obstruction which may be found under any one of the following heads: (1) Compression from without; (2) Blocking up of lumen of canal; (3) Constriction arising from disease of gut wall; (4) Hypertrophy of normal rectal valve, with consequent interruption of lumen of canal and accompanying distortion of gut above obstruction, the latter condition begetting an atonic state. [T. M. T.]

BOSTON MEDICAL AND SURGICAL JOURNAL.

June 20th, 1901

1. A Study of the Food Consumed and Digested by Four Members of the Harvard University Boat Crew in June, 1900. W. O. ATWATER and F. G. BENEDICT.
2. Puerperal Insanity. EDWARD B. LANE.
3. The Home Treatment of Tuberculosis vs. The Climatic Treatment. EDWARD O. OTIS.

1.—Atwater and Benedict have made a study of the dietary, digestion and nitrogen metabolism of 4 members of the Harvard University Boat Crew. The ages of the four men were 20, 22, 19 and 25 years, respectively and their weights 174, 163, 175 and 167 pounds. The men were in normal condition throughout the period of the study. The quantities of solid and liquid excreta were determined for each subject, but the food consumed was determined only for the 4 men taken together. These 4 men used a food supply on the average, per man per day, consisting of 154 gm. of protein, 159 gm. of fats, 474 gm. of carbohydrates. This food furnished a total energy of 4,279 calories, and a fuel value of 3,925 calories. Tables are given comparing the results of this study with the results of similar studies made on the Harvard and Yale University crews while in training in 1898, on the foot-ball teams at Wesleyan University and the University of California, and on Sandow. The studies show that athletes eat considerably more than people in ordinary life, and that their food contains a much larger amount of protein in proportion to the fuel value than is found in the food of people with ordinary muscular strain. Why and to what extent the large percentage of protein represents is not yet fully known. It seems very natural, however, that where great muscular strength and effort are needed there should be corresponding muscular development, and this would be most naturally attained by the use of nitrogenous food. [J. M. S.]

2.—Lane objects to the term **puerperal insanity** to define a distinct type of mental trouble. He is of the opinion that the alienist going through the wards of a hospital for the insane for the first time cannot name the cases of puerperal insanity from objective symptoms. We can diagnose general paresis, mania, melancholia and katatonia objectively; but we must receive the history of recent childbirth before we can make a diagnosis of puerperal insanity. The author believes that the puerperal condition is not an important factor in the causation of insanity. Two hundred and two women patients were received at the Boston Insane Hospital during the past year, of whom only 3% were considered as puerperal cases. [J. M. S.]

3.—Otis is in favor, in the average case, of employing hygienic measures for the treatment of **pulmonary tuberculosis at home** rather than at health resort. In the home climate there is the indubitable advantage of retaining the patient in the same climate in which he has previously passed his existence and in which he must live, at least in a large majority of the cases, the remainder of it. Furthermore, by treating the patient near his usual and accustomed residence we take advantage of the psychic influence of familiar surroundings. Again, the pecuniary factor is a very important consideration with a large number of patients. Comparing sanatorium treatment at home with non-sanatorium treatment in a health resort the author doubts whether the additional climatic excellence compensates for the absence of the sanatorium régime. It is a source of great congratulation to all who are engaged in the treatment of tuberculosis that the prospects of success in the home treatment appear so auspicious. It is the very small minority of the tuberculous who are able or willing to travel far afield for a resort in which to take the cure. The majority, for one reason or another, must, if the hygienic cure is attempted at all, undertake it near home. [J. M. S.]

1.—A. J. Ochsner discusses the cause of diffuse peritonitis complicating appendicitis and its prevention. Diffuse peritonitis is the one complication of appendicitis which produces most deaths. Attention is first called to the anatomical relations of the appendix, and it is shown that this organ is surrounded by more or less immovable tissue excepting in the direction of the general abdominal cavity and here it is in relation with the constantly moving small intestine. The peristaltic motion of the intestine tends to the extension of the inflammation. Nature attempts to put the inflamed parts at rest by diminishing the peristalsis. The point which the author emphasizes throughout his whole address is the fact, that the introduction of food or cathartic into the stomach, by producing peristalsis, has the effect of increasing the spread of the inflammation. Great stress is laid upon the value of gastric lavage for the purpose of entirely emptying the stomach and of withholding all food or medicines by the mouth, rectal feeding being depended upon entirely. The cases in which this mode of treatment has been most satisfactory are those in which the appendix is gangrenous or perforated and in which there is already a beginning general peritonitis. The author maintains that if this form of treatment is closely adhered to that the inflammation will in most instances become circumscribed. The nausea and vomiting will entirely cease after one or two gastric irrigations. The pain will decrease together with the distension and the temperature and pulse will both fall. There is also noticed a marked difference in the abdominal rigidity after the irrigations. The author gives extensive statistics of his own work at the Augustana Hospital where this treatment has been rigidly carried out and records carefully kept. A marked decrease in the mortality of the cases of gangrenous and perforative appendicitis has followed his treatment. The author warns surgeons against the mistake of returning too quickly to gastric feeding. It is also mentioned that peristalsis can very easily result in the rupture of an already localized pus formation.

[J. H. G.]

2.—Newman in his opening address, gives a review of the scientific progress of the year in gynecology and obstetrics. In speaking of anesthesia by lumbar puncture he states that our own writers seem to agree in preferring general anesthesia by chloroform or ether except when, for any reason, these are positively contraindicated and a substitute may be found. Reclus, of France, is a vigorous and logical opponent of the method. The past year has done much to establish the operation of ovarian grafting or transplantation as a logical procedure and one worthy of careful and conscientious experiment. Mauclair concludes from his experiments that auto- and hetero-grafting will be successful if properly performed and the ovary is aseptic. Such grafts should result in modifying menstrual troubles and those consecutive to ovariectomy. Newman quotes the report of Gersuny on his work with injections of paraffin for incontinence of urine due to traumatism. The results have been satisfactory. Cesarean section for placenta previa is advocated by Dudley on the ground that it offers a method of saving two lives in place of risking one or both, and is practically free from danger if thorough asepsis is observed. Among the improved agents for sur-

gical hemastasis should be mentioned the angiotribe, whose claims for recognition rest upon facility of use, greater certainty of hemostasis, more rapid and smooth convalescence, and the avoidance of such objectionable after results as hematoma, granulating and sloughing stumps, adhesion and cicatrization. [W. A. N. D.]

3.—Will be abstracted when completed.

4.—William Roush reports an interesting case of anthrax occurring in a farmer. The patient was switched in the face by the tail of a horse which at the time was suffering from an extensive edema of the head and part of the neck, together with a profuse purulent discharge from the nostrils, mouth and eyes. The animal recovered after two months. The patient developed considerable edema followed by pustules over the cheek. A tube of agar-agar inoculated with the discharge from the wound showed the presence of the bacillus of anthrax in large numbers. The case was treated according to the recommendation of Vock-rency, which consisted in the administration internally of large doses of carbolic acid. Great improvement immediately followed the administration of this drug and the patient made a good recovery. [J. H. G.]

5.—J. E. Rhodes reports an interesting case of throat paralysis occurring in locomotor ataxia of an irregular form. When the mouth was opened and the tongue depressed for examination of the throat the soft palate was in the normal position. On irritating it with a probe, however, the right side of the palate was contracted strongly to the pharyngeal wall drawing the uvula toward the right. The left side of the palate did not respond at all to the irritation but remained relaxed and stationary. There was no anesthesia of the parts. On examination of the larynx the right vocal cord was stationary in the median line, there being a paralysis of the posterior crico arytenoid on the right side. All other conditions of the throat were normal. The diagnosis was an ascending sclerosis causing ptosis of the right eyelid and divergent squint of the right eye, paralysis of the left half of the palate and abductor paralysis of the right vocal cord. [T. L. C.]

6.—E. Fletcher Ingals discusses the difficulties of diagnosing diaphragmatic hernia. The greatest difficulty arises in differentiating this condition from pneumothorax. With the history of traumatism and the symptoms of strangulation the diagnosis may possibly be made but in the absence of these it becomes a difficult question. The condition is congenital in about 38% of the cases. In nearly all the rest it is of traumatic origin. The most important symptoms of the condition are dyspnea, metallic tinkling associated with rumbling and gurgling of gas, the displacement of the heart, the retraction of the abdomen and sometimes succussion sounds. The author then relates a case of his own in which many of the symptoms of diaphragmatic hernia developed suddenly upon the patient, distending the chest by a full inspiration. Many surgeons and physicians saw this patient but no positive agreement could be reached regarding his condition, some maintaining that it was pneumothorax and others, together with the author, thinking it to be diaphragmatic hernia. [J. H. G.]

7.—Chase, from his study of the value of calcium carbide in the treatment of inoperable carcinoma of the uterus concludes as follows: (1) The mass of literature on this subject is misleading; (2) the originators of the treatment were ignorant of the real action of calcium carbide, and had insufficient clinical experience to pass judgment on its value; (3) acetylene has no effect on protoplasm sufficient to support a theory of any specific annihilative action on carcinomatous cells; (4) acetylene has no escharotic effect; (5) acetylene has no bactericidal action upon pathogenic bacteria of putrefaction; (6) the principal action of calcium carbide results from liberated quicklime; (7) lime is not a rational caustic to select, if one is desired, because of its superficial action, the character of the necrosis and the tendency to promote hemorrhage. The metallic salts are more styptic, and their action may be better graduated by proper selection. So the use of calcium carbide may be sufficient to slightly cauterize the tissues. In most cases it has slight therapeutic effect save counteracting the tendency to hemorrhage and promoting contraction; (8) the heat of the actual cautery promises better results because of the firmer cicatrices, resisting carcinomatous invasion and more complete contraction of the wound; (9) calcium carbide is open to the same dangers as other caustics when improperly or too zealously applied; those of producing its corrosive action in the wrong place, fistulae, perforation and fatal peritonitis or occlusion of the ureters. (10) The treatment does not remove the cause of hem-

orrhage nor give more comfort to the patient than other rational lines of treatment; (12) the claims of advocates have not been realized in experience. There is no evidence in theory or practice warranting the conclusions that calcium carbide could ever cure a case of really inoperable cancer of the uterus; (13) the facts regarding the subject should be more widely disseminated to expurge medical literature and to avoid false expectations and fatal delays in inoperable cases [W. A. N. D.]

8.—W. E. Taylor reports an **unusual case of morphinism**. The patient was a man of 45 years, who had used whisky to excess from boyhood. In 1884 he began to take powdered opium in small amounts to allay a pain due to disease of the left shoulder joint. Gradually the amount of the drug was increased until he was taking 30 grains of powdered opium per day. With this he took a considerable amount of alcohol. The patient became fearful of losing his mind and stopped taking the drug suddenly, and of his own volition. He made a complete recovery. [T. L. C.]

9.—L. D. Brose reports two cases of **spasm of the glottis and esophagus in adult life**. His first case was in a patient of 51 years who was suddenly seized with an attack of dyspnea attended by spasmodic crowing inspiration and great mental distress and anxiety. The attack lasted several minutes. The examinations of the throat was absolutely negative. These attacks became frequent and usually occurred between midnight and 4 o'clock in the morning. Finally the symptoms of dysphagia set in with unmistakable evidences of carcinoma involving the lower end of the esophagus and stomach. The post-mortem findings confirmed this diagnosis. The second case was that of a man of 31 years who suffered from an acute attack of dysphasia, and in this case also no evidences of local disease were found. Later, however, positive evidence of tubercular involvement of the upper lobe of the left lung was found. [T. L. C.]

12.—William M. Beach describes a new **proctoscope and sigmoidoscope** which contains an illuminating attachment which greatly aids in the examination of the lower bowel. [J. H. G.]

6. Permanent Gold Preparations. EMMA L. BILLSTEIN.
7. An Improved Bedstead for Invalids. E. E. MUNGER.
8. Excessive Eosinophilia in Trichinosis. A. J. PATEK.

1.—David Riesman reports the case of **pulsation of the uvula** in a patient suffering from aortic insufficiency. This condition is present in a smaller number of cases of aortic regurgitation. Much caution is necessary in order to reveal it, as attempts of retching or swallowing may simulate the pulsatile phenomena. The patient should be instructed to hold the mouth open steadily and breathe quietly. Riesman records here three cases. The phenomenon is of the same nature as the capillary pulse. [T. L. C.]

2.—Nathan G. Ward discusses the use of **formalin in the treatment of suppurative otitis media**. He concludes that by the use of formalin the following results may be obtained. There is an early cessation of the discharge. It breaks up the formation of the granulations and small granulations are discharged by alcoholic solutions. It promotes the healing of ulcerated mucous membrane, abrasions and inflammation of the external auditory canal. It retards, but does not entirely check bone necrosis. [T. L. C.]

5.—George G. Hopkins reports a case of **synchronous amputation of both thighs for gangrene of the feet under special cocainization**. The patient was a man of 68 years. 20 minims of 2% solution of cocaine hydrochlorate were employed. The needle being entered between the fourth and fifth lumbar vertebrae. The result was in every way satisfactory. [T. L. C.]

6.—Emma L. Billstein advises the following method for making **permanent gold preparations**: A mixture of 8 parts of 1% solution of gold chloride and 2 parts of formic acid is boiled three times, then cooled. Very thin pieces of tissue are put into the cooled mixture, which must be kept in the dark. After one hour the tissue is washed in distilled water and then placed in a mixture of 10 parts of formic acid and 40 parts of the distilled water and exposed to diffuse daylight. The reduction occurs in from 24 to 48 hours when the violet tissue is transferred to 70%, and after 24 hours, to 90% alcohol and kept in the dark for at least a week. It is then ready for the final manipulations and may be teased and mounted in acidulated glycerol or cut into sections. [T. L. C.]

8.—A. J. Patek reports a case of a young man of 21 who suffered from **trichinosis**, whose blood count showed 30% of eosinophiles. This is in accord with the observations of Dr. T. R. Brown, corroborated in 20 cases, that in trichinosis the eosinophiles undergo an enormous increase. [T. L. C.]

2. The So-called Traumatic Neurosis. HAROLD N. MOYER.
3. Resection of Superior Sympathetic Cervical Ganglion for Noninflammatory Glaucoma. JOSEPH MULLEN.
4. The Bacteriologic Examination of Clinical Thermometers. RANDLE C. ROSENBERGER.
5. Atypical Pneumonia and Pulmonary Tuberculosis. W. H. BERGTOLD.
6. Electrolysis in Disease of the Skin. F. E. WISECUP.
7. The Nervous Exhaustion due to West Point Training. CHARLES E. WOODRUFF.

1.—Will be abstracted when completed.

2.—Harold M. Moyer discusses the so-called **traumatic neurosis** which he defines is any deviation from the normal in the nervous system, caused by violence. Traumatism may cause disturbance in the central nervous system which may be organic or functional, although the latter is by far the more frequent. The traumatic disturbances which follow traumatism will be found to follow in certain groups, hysteria, anesthesia and hypochondria. It appears to Moyer that concussion neurosis in all its various appellations, is an unfortunate and misleading term; that clearer understanding of functional nervous troubles renders such a term unnecessary; that pain and tenderness of the spine is rarely an evidence of change in the cord, but it usually due to the fatigue of the spinal muscles, or sprain and concussion of the spinal column; that most of the symptoms of spinal concussion are cerebral in origin, and that a correct diagnosis and prognosis may usually be reached by analyzing all such cases after the same manner that we do functional nervous troubles having their origin in nontraumatic causes. [T. L. C.]

3.—Joseph Mullen reports a case of **resection of the superior sympathetic cervical ganglion for noninflammatory glaucoma**. It is claimed that removal of this ganglion is sufficient in glaucoma, because all the sympathetic fibers go to the eye from this ganglion. Panas opposes this view. The operation itself may be performed in two days: First, reaching the ganglion by the posterior triangle, and second, by penetrating the anterior triangle. The immediate effects of excision are relief from pain, contraction of the pupil, increased lacrimation and sweating of the same side of the face. There is always conjunctival injection and oftentimes immediate reduction of intraocular tension. The author's case is similar to the one reported by Panas, and like his, shows a decline in vision. [T. L. C.]

4.—R. C. Rosenberger has made a **bacteriologic examination of clinical thermometers**. His conclusions are of interest. It is possible for the thermometer to be laden with the usual flora of the oral cavity. Such bacteria may retain their capability of growth for an indefinite time, at least 2 months, as shown by Rosenberger's experiments. Many pathogenic bacteria possess similar capabilities, and it is not unreasonable to assume, although the above experiments are not conclusive upon this point, that transmission of bacterial disease by the thermometer is possible. Thermometers are easily disinfected. Where for reasons of economy or otherwise it is impossible to carry out the recommendations of this investigator, the thermometer should be disinfected before and after using. The custom now prevalent in the hospitals of keeping thermometers in disinfecting solutions is to be commended. [T. L. C.]

case of dermatitis vesiculo-bullosa, and has considered the relation of vascular nerve changes to spontaneous gangrene and Raynaud's disease; and more recently Wulff⁷, of Berlin, has reported similar disease of the blood-vessels, causing spontaneous gangrene in a youthful subject. Some will contend that however great the arterial or vascular changes may be, they are secondary to some mysterious trophic influence. There is, of course, much to be said in favor of this view.

Lewaschew's⁸ experiments on animals have shown that five months after irritating the sciatic nerve of an animal distinct changes were noted in the blood-vessels of the part experimented upon, that there was a constriction of the vessels due to the marked changes, first in the adventitia and muscular coat, and later on in the intima of the smaller blood-vessels. Fraenkel⁹ found changes in the blood-vessels three or four weeks after section of the sciatic nerve. It was his opinion that the nerve lesion produces a condition of chronic irritation; that this in turn was responsible for a spasm of the arteries, resulting in a hypertrophy of the walls of the blood-vessels. Among the most recent writers on the subject is Lapinsky,¹⁰ who has shown conclusively that section of the vaso-motor nerves produces a change in the walls of the blood-vessels. He operated upon 14 rabbits, removing various sympathetic ganglia, and also performed resection and ligation of the cervical sympathetic. Following upon these operations he observed a dilatation of the blood-vessels, more marked pulsation, and increased blood pressure. The animals were kept alive for varying periods, from between ten to ninety days. In seven out of the fourteen cases there were marked changes in the larger blood-vessels, consisting of the thickening of the muscular coat and of the elastic membrane. The changes in the smaller blood-vessels and in the capillaries were still more marked. The muscular coat was either atrophic or had disappeared entirely. The intima was thickened and proliferated, the lumen of the blood-vessels being frequently closed. If the animals were killed before six weeks had elapsed since the operation, the degeneration of the walls was not so evident. The nature of the lesion itself and of the sympathetic did not seem to be of any special importance, and it mattered little whether or not the ganglia had been removed at the time the sympathetic was experimented upon. Lapinsky has also done excellent work in showing the dependence of vaso-motor changes upon neuritis. He was able to furnish accurate anatomical evidence of a proliferation of the intima with obliteration of the lumen, and of hemorrhages into the surrounding tissue following upon an experimental neuritis. But granted that the sympathetic and the peripheral nerves exercise an important influence upon the blood-vessels, the question arises whether disease of the blood-vessels may not occur independently of nerve lesions or possibly coincident with them. Such coincidence would not be unnatural if we reflect

that there are several organic and inorganic poisons, such as syphilis and alcohol, which exhibit their deleterious effects upon the blood-vessels as well as upon the nerves.

While Lapinsky is inclined to attach greater importance to reflex neurotic influences, Thoma has established the doctrine that the degeneration of the blood-vessels is largely due to a simple mechanical condition, and that the retardation in the rapidity of circulation and the variations in intravascular pressure are primarily responsible for the changes in the walls of the blood-vessels. Cassirer, who has tried in an impartial way to review the entire literature of the influence of the trophic nerves upon the disease of the blood-vessels, is only able to state, as a final conclusion, that "there is at least every reason to consider the condition of the vaso-motor system in cases of disease of the blood-vessels, particularly of the smaller ones." If this be the result of years of controversy, it will be more fruitful to quit the field of speculative physiology and pathology and to record for the present, in sober fashion, the widespread changes in the vascular system of patients affected with various forms of so-called tropho-neuroses. To this end a few histories and anatomical studies will be briefly reported:

CASE 1.—W. S., 27 years of age, born in Russia: seen for the first time in January, 1898. At that time he complained of a peculiar numbness and tingling sensation in his feet. These would occur at various times during the day and were followed by severe pain and a distinct bluish discoloration of the feet. The patient thinks that for four years before this first examination he has suffered in a similar way. He was employed in a silk factory and was compelled to stand on his feet all day long. The pain was paroxysmal, sometimes lasting only a few moments, at other times it would continue for several hours. He suffered more during the winter than during the summer months, although never entirely free from pain. Holding his occupation responsible for his symptoms, he changed the character of his work and was busy at a sewing machine. After working in this way only a short time and occasionally treading the machine with his bare feet, occasional pain set in in both feet, and he soon noticed that the right one assumed a dark purplish color. The paroxysmal attacks of pain became more and more frequent, the individual attacks lasting longer and longer, until the pain became practically continuous. There is no history of syphilis in this case. The urine was normal, free from sugar or any foreign matter. He had been a heavy drinker for some time, never becoming intoxicated, but rather proud of the fact that he could consume large quantities. The toes of the right foot at the time of the first examination had assumed a dark purplish color. When pricked with a pin the blood that exuded from the toes was almost black. The veins over the arch of the foot were prominent; pulsation could be felt in the arteries at the ankle joint, but not very distinctly. The feet were not sensitive to pressure, even at the time of greatest pain. The left foot was similar in every way, though all the phenomena were somewhat less marked. No sensory disturbance could be detected in either foot in the interval between the attacks. The electrical condition of the nerves and muscles was practically normal. Various therapeutic measures were employed, but without avail. The patient was evidently discouraged and disappeared from observation.

He returned a year and a half later with the history that he had gone to his home in Warsaw, Russia, and had placed himself under the care of a physician. While there, gangrene appeared and one toe after the other of the right foot had to be removed during a period of two months. Soon the toes of the left foot began to give the same trouble, and the big toe of this foot was also removed on account of gangrene. Later on the little toe was removed. The other toes were extremely cyanotic, but were not amputated. The patient felt better and decided to return to New York. When examined after his return, the following condition

7. Ueber Spontane Gangraen bei jugendlich n Individuen, Berlin Surgical Society, Dec. 10, 1888, reported in Deutsche Med. Wochenschr. No. 5, 1901, p. 68.

8. Virchows Archiv, Vol. 92, p. 152.

9. Centralblatt f. allg. Pathologie und Path. Anatomie, 5, 5, 1—quoted by Cassirer.

10. Deutsche Zeitschr. f. Nervenheilkunde Vol. XVI, p. 1.

was noted: The right foot presented a reddish purplish appearance, with veins still prominent and arteries with distinct but weak pulsation. The left foot was of a much darker appearance; the only three toes which had not been amputated were extremely cyanotic.

At this time the patient was working in a cigar factory. He was under observation just one month when severe pain and gangrene appeared on the inner and plantar surface of the left foot. On account of the pain and marked cyanotic appearance of the foot, amputation had to be resorted to, and this was done by Dr. Lilienthal, the patient making an uneventful recovery. Previous to the amputation of the foot, the patient began to complain of pain and numbness in the index and middle finger of the right hand. These fingers would get perfectly white and were practically corpse fingers, in marked contrast to the deep cyanotic color of the other fingers and rest of the hand. The pulse at the wrist did not alter its character appreciably during the entire attack. It was of great interest to us, however, that at this same time a marked phlebitic swelling occurred just below the elbow. This gradually disappeared under proper treatment.

The paroxysmal attacks of pain, the recurrent forms of local syncope and asphyxia, followed by symmetrical gangrene, the absence of marked sensory changes and of a reaction of degeneration in the nerves and muscles of the affected parts, made the diagnosis of Raynaud's disease certain enough. But, even if there were to be a difference of opinion as to the exact labeling of this special case, the marked arterio- and phlebo-sclerosis was of special interest. On carefully examining the removed tissue, we could not find a single artery or vein, large or small, that was not diseased. Slight degenerative changes were found in some of the nerve fibres. Excessive alcoholic indulgence and the peculiar occupation of the individual must be considered the chief etiological factors. With alcohol as a predisposing cause of vascular disease, the constant use of the extremities may be considered to be the additional exciting cause. Moreover, as soon as the patient changed his occupation and became a cigarmaker, necessitating the more active employment of the hands and fingers, the disease became evident in the upper extremity. Exposure to cold may also have played a rôle, and in view of the diseased condition of the blood-vessels, reactive circulation could not be easily established in parts that were improperly nourished, the obliterating endarteritis in this case was evidently not of recent date. An examination of the specimens showed some of the vessels almost completely obliterated by dense sclerotic tissue, while all possible and advanced stages of an obliterating endarteritis could be made out. The presence of phlebitic swelling in the right fore-arm, coincident with the first symptom of the Raynaud type in this same extremity, would also go to prove the intimate dependence of the latter upon the former. The patient, on close questioning, also stated that he had frequently had these lumps in the lower extremity before the later symptoms had been carefully noted. It will not be necessary to claim that Raynaud's disease is always due to vascular changes, though Barlow, Dehio, and even Raynaud himself have reported such changes in subjects of this disease. Allowing for marked trophic and vaso-motor influences, the case just reported seems to us to furnish good evidence of the intimate relation between the vascular changes and the grave disturbances in the nutrition of the peripheral parts.

CASE 2.—S. L., a tailor, 31 years of age, married 7 years. Family history negative, as far as any neurotic taint is concerned. Smokes a pipe and drinks beer very freely. No history of any venereal trouble. Has worked at a sewing machine for 4 years, but gave up this occupation 3 years ago. Has never suffered any exposure to cold. Four years before the first examination he claims that he had suffered with occasional burning pains along the inner border of the left foot and drawing pains of the left calf. These attacks were infrequent at first and lasted about half a day. He noticed that at times a red patch would appear over the inner border of this same foot, without any distinct pain in walking. Two and a half years ago he began to suffer from redness and swelling in the big toe of the left foot, which was accompanied by a marked burning sensation. The pain, the redness and the swelling were constant, but were made distinctly worse on walking. The trouble was supposed to be rheumatic, and the treatment was in accordance with this supposition. This treatment was interrupted by the appearance of an ingrowing nail on this same toe. The nail had to be removed, and a black suppurating slough developed, the gangrenous area spreading toward the end of the toe on the outside. This area was excised and the bone thoroughly scraped. Gangrene, however, continued to spread, so that it became necessary to remove the nail and one phalanx, which was done on January 21, 1899. The patient had been in the hospital three weeks, and as the amputation wound refused to heal, the sloughing skin and a piece of the proximal phalanx were removed. During all this time the patient had severe pain, and the other toes of the same foot became reddish blue, were swollen and were more or less painful. In May 1899 the proximal phalanx was removed under chloroform and the wound bid fair to heal. Later on numerous incisions had to be made for evacuation of the pus. The patient insisted on returning to his work, but ulcers were developed between the base of the second and the third toes on the dorsum of the foot. The blueness, pain and swelling were growing constantly and were especially severe when the foot was in a dependent position. The heart, lungs and kidneys were normal; the patient weighed about 141 lbs. and was emaciated in appearance. There was a general atrophy of the left limb from the hip down. This atrophy may partly have been due to disuse, as the patient had practically not used this limb for a period of four and a half months. The deep and superficial reflexes were normal. The left foot, when in a dependent position, became cyanotic; when elevated, it gradually grew paler, but remained painful. The great toe is absent, and the others are swollen, so that the lines over and around the articulation are lost. The nails are thick, round in shape and with a tendency to become ingrown. Under the dorsum of the right foot at the head of the first metacarpal bone is a round circumscribed ulcer, three centimetres in diameter, which involved the entire thickness of the skin. The borders are not undermined, but sharp, and bleed easily when the foot is dependent. At the base of the muscles is a yellow-grayish slough that does not bleed easily. Around the ulcer the skin has a reddish blue color, which disappears slowly and returns slowly on pressure. On the dorsum of this foot and base of the second and third mediodorsal phalangeal articulation is another ulcer similar in every respect to the one just described, only differing in size and shape. The pain became so severe in this case and the ulcers refusing to heal, various therapeutic measures were tried, and the leg was amputated above the knee joint by Dr. Gerster. The popliteal artery, vein and nerve, the anterior and posterior tibial arteries, veins and nerves, together with the plantar arteries and nerves and various tissues of the foot, were immediately removed and examined.

In this case also, all the veins and arteries were in a condition which might best be designated as a marked arterio- and phlebo-sclerosis. The under popliteal nerve was entirely normal. Only in the neighborhood of the ankle joint were a few degenerated fibres in the anterior and posterior tibials. There was a distinct inflammation of the nerves on the dorsal and plantar portion of the foot. In this case again, if we were interested in the diagnosis of erythromelalgia, a hue and cry would be certain to be raised; although the swelling, the redness, the pain,

the marked hyperesthesia, all increasing when the foot was in a dependent position, would be in agreement with that diagnosis. But we will not insist on it, since the clinical picture was evidently altered through the presence of an ingrowing nail, and possible infection of the foot leading to the ulceration and gangrene. There would be no objection to classifying this special case as a representative of the simple obliterating endarteritis of Friedländer; and to meet all just criticisms, it may simply be inferred that the earlier stages of obliterating endarteritis give rise to symptoms which are very similar to those included under the term of erythromelalgia. The occurrence of marked pain in these cases is of some interest. It would be natural to connect this with a terminal neuritis, as Weir Mitchell has done in his classical accounts of erythromelalgia; but one cannot escape the conclusion that the terminal neuritis may at times be secondary to this marked alteration of the blood-vessels, with subsequent malnutrition of all the tissues, including the nerves. In the case just referred to the parent trunks were normal, and changes were found only in the more peripheral portions. When gangrene and ulceration appear the neuritis may be attributed, in part, also to the effects of the infection.

CASE 3.—The patient, Mrs. S. I., 29 years of age, was referred to Dr. Wiener by Dr. Goldenberg. She was born in Germany; married 8 years; inclined to obesity, and presented gouty manifestations. Short and thick-set in stature, she easily tires and suffers from palpitation and dyspnea when she attempts to walk rapidly or to climb a flight of stairs. Of the four children born to her none is living. During first pregnancy she had a bad fall in the seventh month. The child was born at term and died shortly after birth. With the second child labor was difficult; the child was born alive, but died on the following day. The third was born at full term and died a few days thereafter in convulsion. The fourth child lived to be six months of age and then died in an attack of pneumonia. The patient has never had any serious illness and gives no history of syphilis or of any venereal infection, however suspicious the history may be. Her mother died at a very early age of unknown disease. Father is living and well. The parents of the patient have had seven children; of these seven, five are living and perfectly healthy. In regard to the other two, one died of meningitis, complicating influenza, and the others of pernicious anemia. The patient's husband is living and has been free from serious illness. In the spring of 1900 the patient's foot began to itch in a very annoying manner, so that she often was compelled to remove her shoes during the day to relieve the itching by scratching. It was especially severe in the neighborhood of the small and middle toes of the right foot and the small and big toes of the left foot. At first there was no pain, but gradually the pain appeared after scratching. After a period of three weeks, following upon the mechanical irritation produced by scratching, excoriated areas appeared over the left foot. The ordinary treatment by dry powders was of no avail; the excoriations gradually developed into ulcers, and the patient requested treatment at the Vanderbilt Clinic. She was put under thorough anti-syphilitic treatment, which had no effect on the healing of these ulcers. The pain became continuous, was burning in character and so severe that she was unable to obtain a night's sleep. After further treatment by Dr. Goldenberg, consisting of ichthyol ointment and cold dressings, which also proved unavailing, the patient was sent to Mount Sinai Hospital, where, after remaining at rest for a few weeks, the ulcers gradually healed; but as soon as she was up and about again, the same condition returned. It was then decided to amputate the big and second toes upon which the ulcers existed. Considerable relief followed upon this, and the patient has been up and about for six months. The urine was examined several times and found to be normal, only once a very slight trace of sugar was made out, to which, how-

ever, no importance could be attached. No distinct sensory disturbances were ever detected. The deep and superficial reflexes were always normal. Distinct and good pulsation was present in this foot. The toes just before amputation were very much swollen and of a reddish purple appearance. The base of the ulcers was covered by a thin grayish purulent-looking mass. The edges were not undermined or thickened.

A microscopic examination of the tissues taken from the amputated toes shows an obliterating endarteritis in its earlier stages, and also a nerve end neuritis. No normal nerve fibres could be made out in the many specimens that were examined. The tissues were infiltrated with round cells and showed an active inflammatory condition. This case demonstrates the earlier presence of vascular disease in association with nerve endneuritis and with trophic disturbances. It is not unimportant to note the early and persistent itching. The scratching, the mechanical irritation, as well as the infection, evidently led to the development of ulcers in parts embarrassed by a defective circulation, due to diseased blood-vessels.

In the three cases just reported somewhat in detail, the relation to the trophic disturbances and the vascular disease seems to be evident enough; but since our attention has been directed to the observation of the blood-vessels in the extremities, other and lesser conditions have been met with which may properly be attributed to lesser and possibly recoverable affections of the peripheral blood-vessels. Some time ago we had under observation a lady of 55 years of age, who had been treated for an attack of hemiplegia, due to embolism. The patient had a marked general arterio sclerosis in addition to the valvular lesion, without any renal complications. She had recovered from the hemiplegia and is now able to get about without assistance. Her general health is good, but she is troubled from time to time by spasmodic attacks of severe pain in the fingers of the right hand, followed by numbness and pallor of these fingers. The attack generally does not last more than a few hours. During several such attacks one of us was called to see her, and found that the fingers were absolutely numb and resembled in every respect the corpse fingers of Raynaud's disease. Each one of these attacks has been promptly relieved by the administration of hot baths, vigorous massage, and small doses of iodides. The attacks could justly be likened to those of Raynaud's disease, but the matter is referred to here merely to show the probable dependence of such symptoms upon arterio sclerosis of the peripheral vessels. It is a matter for surprise that such attacks are not more frequently referred to in association with cardiac and arterial disease in the senile period.

In another elderly lady of 60, suffering from severe diabetes and treated in conjunction with Dr. Janeway, the most distressing symptoms were frequent burning sensations, numbness and occasionally a cold feeling in the lower extremity. We might have been satisfied merely to record these as ordinary rheumatoid pains, for there was also a gouty rheumatic element in this case; but, bearing in mind the possible disease of the peripheral arteries, we watched carefully the pulsations of the dorsal artery of the foot and often found its beat feeble. Relief in this case was only to be had from active massage

and the application of intense heat. There can be little doubt that such symptoms as these are due to interference with the peripheral circulation. If we bear in mind the frequency of gangrene in diabetes, the occurrence of such symptoms as we have just described, denoting a lesser degree of vascular disease, becomes a matter of more than passing interest.

It would indeed be well to pay greater attention to the arteries of the lower extremities, for not only are such rare types of disease as intermittent claudication known to be associated with arterio sclerosis in the lower extremities, but Thoma's interesting researches have shown quite conclusively that many of the vague rheumatoid affections may be considered to be due to an angiosclerosis.

Whatever theory we may hold with regard to the influence of trophic and vaso-motor fibres upon disease of the blood-vessels, the experiences here reported seem to argue in favor of an intimate relation between the disease of the peripheral blood-vessels and many of the tropho-neuroses; but whether such disease be primary or secondary must be left to further investigation.

THE FREEZING-POINT OF URINE: ITS DETERMINATION AND THE INFERENCES WHICH MAY BE DRAWN FROM IT.*

By J. H. HUDDLESTON, M. D.,
of New York.

History.—The determination of the freezing-point is called more technically cryoscopy from kryos, cold, and skopein, to see.

As early as 1870 Bouchard employed this method in the examination of the urine, and in 1872 and 1873 Malasser and Hamburger followed in the work. In 1891, after an interval, Dreser added his name to the list of investigators, and in 1894 Koranyi, of Buda Pesth, began the careful studies which culminated in an elaborate paper published in the *Zeitschrift fuer Klinische Medicin* in 1897 and 1898. Since then there has been some steady progress along the line of this work, and at the International Medical Congress in 1900 the method of investigation received its first extensive public notice. Bouchard, Vaquez, Bousquet, and, most recently, Claude and Balthazard have all published notable papers. Outside of Germany and France, however, there has been comparatively little attention paid to the results obtained, and this is my excuse for the following paper:

Theory.—The theory of Urinary Cryoscopy is based on (A.) Raoult's theorem, now an accepted law of chemistry, much used since 1888, and (B.) Koranyi's theory of molecular exchange in the convoluted tubules of the kidney.

A. Remsen, in his theoretical chemistry, states Raoult's law as follows: "One molecule of any compound when dissolved in one hundred molecules of a liquid lowers the freezing point of the liquid by an amount which is nearly constant." Inferentially the same number of molecules of urea or of sodium chloride dissolved in urine cause the same lowering of the freezing point. This marks at

once a significant difference from the specific gravity of the urine. A few heavy molecules would notably increase the specific gravity, but would affect but little the lowering of the freezing point. Blagden has stated the law in this form: "If two different substances are contained at the same time in the same solution the lowering of the freezing point of the solution is the sum of the lowering of the freezing point which one substance would cause and that which the other would cause." The experiments of Koranyi on mixtures of solutions of sodium chloride and of urea have confirmed this law for those substances, and, to a certain degree, therefore, for urine. If T = the temperature of the freezing point of urine, and therefore the lowering of the freezing point below 0° , then $C T$ (in which C represents some constant) = the number of molecules in unit volume of urine, and if V = the amount of urine passed in twenty-four hours, $C T V$ = the total number of molecules of all sorts passed in solution in that time. Urea and the other organic compounds form about 7-12 of the average solid content of urine, sodium chloride about 3-12 and the sulphates, phosphates and metallic bases about 2-12. Of these sodium chloride is the only one which, passing unchanged through the body, does not represent any metabolism. If T' = freezing point of a solution containing the same amount of sodium chloride as the particular specimen of urine, $T - T' = T''$ = the lowering of the freezing point due to the rest of the dissolved matter including all the complex matter of the urine, and, as before, $C T'' V$ = the total number of the complex molecules, those concerned in metabolism, passed in twenty-four hours. If W = weight of the person expressed in Kilos. $(C T V) \div W$ = the number of molecules excreted per kilo of weight or the total molecular diuresis, and $(C T'' V) \div W$ = the number of complex molecular diuresis.

These symbols may be put in figures; in an actual normal urine T was found to be $-1^{\circ}.50$; V , 1500; and W , 60; $-0^{\circ}.613$ has been found to be the freezing point of 1% of sodium chloride, and the freezing point of any per cent. Cl of sodium chloride is $Cl \times .613$. In this specimen Cl was $= .4904$ and $T'' = T - T' = 1.50 - .49 = 1.01$; $.008$ and the freezing point was therefore $.8 \times .613 = .4904$ and $T'' = T - T' = 1.50 - .49 = 1.01$; $(C T V) \div W$ then was $(C \times 150 \times 1500) \div 60 = 3750 C$ and $(C T'' V) \div W = (C \times 101 \times 1500) \div 60 = 2525 C$. In each case C , of course, is a constant which is eliminated in comparisons. Normally T varies from $-1^{\circ}.30$ to $-2^{\circ}.20$ centigrade, $(C T V) \div W$ roughly from 3000 C to 4000 C and $(C T'' V) \div W$ from 2000 C to 2600 C .

B. Koranyi's theory is first, that there is filtered through the walls of the glomeruli of the kidney water containing sodium chloride in such amount that the solution has the same osmotic tension and therefore the same freezing point as the blood plasma, and second, that as this solution flows through the convoluted tubules and Henle's loops, it there returns to the blood a certain amount of water and a certain number of molecules of the sodium chloride and receives exactly the same number of molecules of more complex substances.

*Read before the New York Academy of Medicine June 6, 1901.

In general language, the solution there becomes concentrated and takes on the character of urine. If the glomerular filtration is rapid the flow of urine is rapid and the rate of molecular interchange in the tubules per unit of urine is slow. Such would be the case with high arterial tension. On the other hand, if the glomerular filtration is slow the flow of urine is slow and permits a high rate of molecular interchange in the tubules per unit of urine. Such would follow in renal stasis or in injury to the glomerular wall as in glomerulo-nephritis. Again, no matter what the rate of urinary flow, if the epithelium of the tubules performs its work imperfectly or obstructs the interchange, the rate of that molecular interchange must be lowered. Such would naturally follow in tubular nephritis or in any other organic or functional affection of the tubules.

$(C T V) \div W$, as was said, represents the total molecular diuresis, i. e., it represents the glomerular filtration, increasing in value when that is rapid, decreasing when it is slow. With high arterial tension, for example, it may go up to 6000; with renal stasis it may go down to 300. The complex molecular diuresis is represented by $(C T'' V) \div W$ and the rate of molecular exchange by the ratio of the total molecular diuresis to the complex molecular diuresis, i. e., by the ratio of $(C T V) \div W$ to $(C T'' V) \div W$ or $T \div T''$. If the swiftness of the urinary flow diminishes $(C T V) \div W$ is less, and there is opportunity for greater molecular interchange, so $(C T'' V) \div W$ increases and the ratio $T \div T''$ therefore diminishes. A nephritis limits molecular interchange, and $T \div T''$ therefore increases. Normally this ratio varies from 1.49 to 1.69. Another ratio which was studied in great detail by Koranyi is $T \div Cl$, in which Cl is the per cent. of sodium chloride in the urine, and the ratio therefore represents the total number of molecules in unit volume compared with the number of chlorine containing molecules in the same volume. This ratio was found to vary normally between 1.23 and 1.69. Still another ratio of importance is that expressing the amount of sodium chloride which is equivalent to all the matter dissolved in urine. As the freezing point of a one per cent. solution of salt is .613 T would be the freezing point of a $T \div .613$ per cent. of salt and $(V T) \div 61.3$ grams would be the amount of salt in V c. c. of a solution freezing at T , i. e., $(V T) \div 61.3$ represents the equivalent desired. This varies normally from 30 to 50.

We have, therefore, according to Raoult's law and Koranyi's theory, certain ratios, each capable of being expressed in figures, each representing the ability to perform a special renal function, each varying naturally within certain limits, and each denoting by its variation outside of those limits a definite failure of function.

Arguments.—The theory is too precise and too valuable if true not to demand the closest examination.

A. Raoult's law is not universal in the form stated; it is exact for a very large number of organic substances, but it is not found to hold good for the watery solutions of inorganic salts, acids and bases; such solutions act as if they contained

a larger number of molecules than is indicated by their formulas; in fact, with these substances, "the number of 'active molecules' is increased by the dissociation of the compounds into their ions; when the degree of the dissociation is determined, however, the law holds exactly when applied to these solutions also."

On the other hand, it is probable, according to Loomis, that molecules of albumen, and perhaps of certain normal urinary constituents, lump themselves together—several acting with reference to freezing like a single molecule—and therefore lowering the freezing point less than would be expected. $Cl \times .613$ does not without some corrections represent the exact freezing point of any percentage of sodium chloride, as the reduction of the freezing point is not exactly proportional to the per cent. It is probable, therefore, that the results are not precise, but that they are comparable among themselves. Further confirmation of the applicability of the law to all of the complicated bodies in urine is needed.

B. That the important glomerular function is to filter a salt solution from the blood seems to be supported by the best evidence obtainable. Starling recounts a number of experiments made by himself which tend to show that the glomerular epithelium may be looked on as a simple filtering membrane resembling a membrane of gelatine, and that when the pressure in the glomerular capillaries rises above 25 to 30 m. m. of mercury filtration takes place through the epithelium into the tubules—the filtrate representing simply plasma minus proteid.

C. That the water excreted in the glomeruli is partly absorbed in the convoluted tubules is supported by the facts (1) that in a general way the convoluted tubules of animals which pass a concentrated urine are long and of those which pass a dilute urine are short, and (2) that the concentration of urine lessens with the rapidity of excretion.

D. On the other hand, the theory of an exact interchange of one complex molecule for one salt molecule in the convoluted tubule is supported by little direct evidence. The physical law of the conservation of energy is the principal support. By the general theory of osmosis the work performed through the tubular membrane is least if we assume that exact exchange. No vital action is necessary for this, but it is not possible to assert that none takes place. Koranyi, however, performed certain animal experiments which involved the analysis of the blood serum as well as of the urine and found that the ratio of chlorine to non chlorine holding molecules in the blood is inversely what it is in the urine, and, therefore, in accordance with the theory.

E. The principal proofs of the value of cryoscopy must naturally be found in clinical experience with the method in the accordance of its results with those of chemical observations made in other ways as with the methylene blue test, and with autopsies. A certain number of autopsies are on record in which the conditions present in the heart and kidneys were predicted by the results of cryoscopy, but too few have employed the method for the clinical comparisons to be regarded as at all well worked out. Koranyi's papers of 1897 and 1898

were, however, founded on some thousand observations: Bouchard added a great number, and observations are now being made by many competent workers. The writer's own experience is limited, but as far as it goes certainly testifies to the agreement of inferences from cryoscopy with those drawn from more usual clinical methods. Comparisons are, however, often extremely difficult. Urinary cryoscopy is a test of function. A kidney may, for example, have a large portion useless from disease and yet be able to perform its work perfectly. It is quite within the range of probability that during certain periods of chronic nephritis there may be no renal insufficiency, and yet during those times cryoscopic examination would point to a normal condition. Finally, a milk diet, an excess of salt ingested, excessive sweating, pregnancy and convalescence from acute disease, may furnish figures suggesting a renal insufficiency which may or may not exist.

Uses.—It would be unjust to urinary cryoscopy to omit paying some attention to its pre-eminence as a test of function quite independent of structure. Startling revelations in gross or microscopic investigation of the pathological anatomy of an organ are hardly now to be expected, but intimate studies of the constantly varying capacity of an organ to do work, at least of such an organ as the kidney, have the merits of rarity and novelty and inspire the hope which springs from a new field.

A. It is in uncomplicated disease of the heart that the new method has won its greatest approval. Koranyi even insists that the investigation of a cardiac case is incomplete until the freezing point of the urine and the per cent. of sodium chloride in the urine have been determined. He has found that passive hyperemia of the kidney is earliest and most clearly demonstrated by a high value of the ratio $T \div Cl$, and that therefore the ratio may be used as a test of the effect of activity on a cardiac case. If in a patient doing a certain amount of work this ratio is over 1.7, the person should be kept quiet, person should be put to bed. This is true quite regardless of whether dyspnea or cyanosis are present or absent. The reason for this variation is admirably explained by the theory; if the circulation in the kidney is hindered in the slightest, there is less rapid excretion of serum into the glomeruli, a less rapid flow, therefore, down the tubules, a longer stay in the convoluted tubules, a more prolonged and extensive interchange of complex molecule for salt molecule, a diminution in the salt left in the urine and an increase in the fraction $T \div Cl$. In uncomplicated disease of the heart the ratios $(TV) \div W$ and $T \div T''$ are both high if there is high arterial tension, and both low if there is low arterial tension, and the same is true if the tension is due to arterial sclerosis, intoxication, or nervous derangements.

B. In uncomplicated diseases of the kidneys a study of the comparative values of certain of the ratios named may reveal a glomerular nephritis as distinguished from a tubular, a distinction hitherto hardly possible. The former form of nephritis is inferred from a low value of $(TV) \div W$ and a normal value of $T \div T''$. The degree of glomeru-

lar or of tubular obstruction may be estimated to some extent by the value of the ratios, and especially the gravity of the prognosis may be judged by the value of the ratio $(T''V) \div W$; if this falls below 500 death is said to be imminent.

C. In combined disease of the heart and kidneys the values of certain ratios point to the organ chiefly at fault—or insufficient at any moment. Even the freezing point alone is of service here. If, for example, there is anasarca and a freezing point lower than normal the kidneys are not at fault; if the freezing point is within the normal limits the kidneys are somewhat affected, and if the freezing point is above normal the kidneys are notably diseased. It is of importance, too, that the figures show that a large flow of urine following medicine may not mean a large elimination of the complex molecules.

D. In effusion into a serous cavity the ratio $T \div Cl$ indicates by its value whether absorption or exudation is going on, diminishing in the former case and increasing in the latter. In this, of course, the observation is similar to that long made about the increase or decrease of chlorine in the urine.

E. It is to Bouchard that we owe the application of the method to the study of metabolism. The molecule of albumen with an atomic weight of six thousand is split up in the body in the course of the various nutritive processes, part of the carbon going off through the lungs, part through the intestines, and part through the kidneys; the sulphur goes off partly as sulphate, and the phosphorus partly as phosphate through the kidneys. In the process of breaking up the molecule tends constantly to what may be called its lowest term, the molecule of urea, with an atomic weight of sixty. All urine contains by-products produced in the course of this reduction, but where the processes of nutrition are incomplete the urine contains more of these by-products; where the processes of nutrition are complete the urine contains less. All these by-products have atomic weights which are higher than that of urea. In other words, the average atomic weight of the various organic molecules of the urine tends toward sixty as a limit, a limit which, however, is not reached in any case. If by any means, as by cryoscopy, one may obtain the number of molecules in a specimen, obviously by taking the weight of all the matters dissolved and dividing that by the number of molecules, the average molecular weight may be obtained. This can be done, and in the same way the average molecular weight of the complex molecule can be obtained.

(If the lowering of the freezing point of a solution is proportioned to the quantity of the substance in solution and to its molecular weight the following proportion has been found to be true: If M = the weight of the substances in 100 c. c. of water and m = the average molecular weight and T the freezing point, $T : M = K : m$, where K is a constant established for every solvent and for water equal to 18.5; $m = (18.5 \div T) M$. If $m' = 118.5 (M - Cl) \div T''$ for the normal urine earlier quoted $118.5 (4.6 - 8) \div 101 = 66$. M is obtained by multiplying the last two figures of the specific gravity 1021 by Häser's coefficient 2.33.)

Bouchard has found that normally this molecular weight of the average complex molecule varies from 62 to 68 and that pathologically it may reach 130: it is regularly high in certain fevers and diseases of the lungs, liver, and kidneys. It is a confirmation of the theory of cryoscopy that these normal figures 62 to 68 are also obtained by calculating them from the known composition of urine. The importance of this use of cryoscopy lies, of course, in the estimate it gives of the power of the body to assimilate.

Practice.—The values sought are the following:

T = freezing point of the urine; normally — $1^{\circ}.30$ to $2^{\circ}.20$ C.

Cl = percentage of sodium chloride in the urine, usually .80 to 1.50.

V = 24 hour amount of urine.

W = weight of person in kilos.

M = weight of matter dissolved in 100 C. C. of urine, = $2.33 \times$ the last two figures of the specific gravity. Of these five values only T and Cl are essential.

From these are obtained the following:

T' = freezing point of a solution containing the same amount of sodium chloride as the urine, = $.613 \times$ Cl.

T'' = lowering of freezing point due to the non-chlorine containing molecules of the urine, = $T - T'$.

m = average molecular weight of M.

m' = average molecular weight of M less the chlorine molecules = $(18.5 (M - Cl)) \div T''$: normally 62 to 68.

The following ratios are diagnostic:

(a) $(V T) \div W$ = total molecular diuresis: normally 3000 to 4000.

(b) $(V T'') \div W$ = complex molecular diuresis; normally 2000 to 2600.

(c) $T \div T'' = [(V T) \div W] \div [(V T'') \div W]$ = ratio of total to complex molecular diuresis: normally 1.49 to 1.69.

(d) $T \div Cl$ = ratio of total molecules to chlorine containing molecules: normally 1.23 to 1.69.

(e) $(V T) \div 61.3$ = the sodium chloride equivalent of the non-chlorine molecules dissolved in the 24-hour urine: normally 30 to 50.

It is obvious that $T \div T''$ (Bouchard's ratio) and $T \div Cl$ (Koranyi's ratio) differ in that the denominator in the first fraction represents the number of molecules not containing chlorine, and in the second fraction the number of molecules containing chlorine. Obviously, too, $T \div T''$ will increase just in proportion as $T \div Cl$ diminishes, and vice versa. Moreover, as T'' cannot be obtained with as much exactness as Cl, the Koranyi ratio seems preferable for use. The advantage of the Bouchard ratio is in the concept to which it gives rise by its formation of the actual comparison between the numbers of molecules which pass the glomerular diaphragm and the number which pass the tubular diaphragm.

Method.—As has been pointed out, there are two determinations especially needed: (a) the freezing point T. (b) the percentage of sodium chloride Cl.

(a) The method of obtaining the freezing point with which the writer began was one advised by Prof. E. H. Loomis, of Princeton, who has for a

long time been interested in the observation of freezing points of solutions. His recommendations are as follows:

1. Use a double-walled test tube,—that is, place the test tube in another tube, which is a trifle larger, keeping them apart with a rubber band. The inside tube should be bottle-shaped at the bottom so that the stirrer may go to the lowest point of the tube and dislodge any ice that would otherwise tend to mass itself there. It should be about seven inches long and one inch wide. The thermometer may be held in place by thrusting it through a cork. The tube is provided with a "ring and feather" stirrer. This is easily made by taking a piece of wire and bending it at one end into a round loop about $\frac{5}{8}$ of an inch across. Then one side of a goose feather is stripped off and the feather is wired to the outside of the ring.

2. There is then prepared a mixture of finely-pounded ice and water of the consistency of a thick slush. This is put in a vessel of glass heavily wrapped with felt. Salt enough is added to this mixture so that the temperature of the mixture after thorough stirring is approximately that of the freezing point of the urine, determined roughly by a preliminary experiment.

3. The test tube is filled about one-third full of urine. The thermometer and stirrer are inserted, the whole is exposed to the freezing mixture until its temperature has fallen about three to four-tenths of a degree below the temperature at which the urine freezes. The tube and contents are then transferred to the bath described in 2, and a tiny crystal of ice is dropped into the over-cooled urine. This at once begins to freeze and the temperature rises, finally stopping at the freezing point. This requires about one minute and a reading of the thermometer is then taken. Uniform stirring is maintained. Loomis has found it necessary for the fine work involved in determination of molecular weights to have an electric vibrator tap the thermometer continually so as to ensure perfect mobility to the mercurial column. This method enables one to determine the freezing point within 1-1000 of a degree centigrade. The exact reading is taken through a microscope focussed on the thermometer scale. Prof. Loomis says that the instruments made by R. Fuess, of Berlin, Germany, are the only ones which have given him satisfaction. A suitable one graduated in 1-100 degrees centigrade may be imported for about \$25. As the writer had never seen a thermometer intended for this purpose he had one constructed by a reputable New York manufacturer of scientific instruments, which registers in tenths the degrees from 0° to -4° centigrade. The divisions are sufficiently large to enable one to read to fortieths, and the thermometer is a little less than six inches long. It has a lens front, but this proved to be a distinct disadvantage. Otherwise it was a most convenient instrument, but after some use it was compared with Dr. Loomis' standard thermometer and found to have so large an error that all work done with it was useless. It has been found helpful to use for the double tube two vials with flat bottoms, and to put in the outer sufficient absolute alcohol so that its level is practically the same as that of the urine in the inner tube. A sim-

ple spiral of wire works very well as a stirrer, and the thermometer may be hung in the urine by a cord. Foreign workers have advised cooling the urine by ether or carbon bisulphide rapidly volatilized by a current of air, but with this method the writer has had no experience. The mercury falls slowly to a certain point and then suddenly with or without the addition of the particle of ice rises to the freezing point; while it is rising it is especially necessary to keep the urine well stirred. After a moment when more or less of the urine is frozen the temperature gradually falls again to correspond with that of the freezing mixture. It is necessary, therefore, to take the highest point to which the mercury ascends as the freezing point. The time necessary for this observation varies from fifteen to twenty minutes. Certain precautions are necessary: the urine must not have undergone any fermentation, as the number of molecules and the freezing point are affected by that change; if the freezing throws down a precipitate, the urine must be diluted until that action is avoided; no antiseptics and no medicines must be in the specimen.

(b) The percentage of sodium chloride is determined by Volhard's method, and this is described in Hammarsten's Text-book of Physiological Chemistry as follows:

"All the chlorine from the urine acidified with nitric acid is precipitated by an excess of silver nitrate, filtered, and in a measured part of the filtrate the quantity of silver added in excess is determined by means of a sulphocyanide solution. This excess of silver is completely precipitated by the sulphocyanide, and a solution of some ferric salt, which, as is well known, gives a blood-red reaction with the smallest quantity of sulphocyanide, is used as an indicator.

"We require the following solutions for this titration: 1. A silver-nitrate solution which contains 29.075 grms. AgNO_3 per litre and of which each c. c. corresponds to 0.01 gm. NaCl or 0.00607 gm. Cl ; 2. A saturated solution at the ordinary temperature of chlorine-free iron alum or ferric sulphate; 3. Chlorine free nitric acid of a specific gravity of 1.2; 4. A potassium-sulphocyanide solution which contains 8.3 grms. KCNS per litre, and of which 2 c. c. corresponds to 1 c. c. of silver-nitrate solution.

"The determination of the chlorine in the urine is performed by this method in the following way: Exactly 10 c. c. of the urine is placed in a flask which has a mark corresponding to 100 c. c.; 5 c. c. nitric acid is added; dilute with about 50 c. c. water, and then allow exactly 20 c. c. of the silver-nitrate solution to flow in. Close the flask with the thumb and shake well, slide off the thumb and wash it with distilled water into the flask, and fill the flask to the 100 c. c. mark with distilled water. Close again with the thumb, carefully mix by shaking, and filter through a dry filter. Measure off 50 c. c. of the filtrate by means of a dry pipette, add 3 c. c. ferric-salt solution, and allow the sulphocyanide solution to flow in until the liquid above the precipitate has a permanent red color. The calculation is very simple. If we always use 10 c. c. for the determination, and always 20 c. c. AgNO_3 , and dilute with water to 100 c. c., we find the quantity of NaCl in 1000 parts of the urine by subtracting the number

of c. c. of sulphocyanide (R) required with 50 c. c. of the filtrate from 20. The quantity of NaCl p. m. is therefore under these circumstances $= 20 - R$, and the percentage of $\text{NaCl} = (20 - R) \div 10$."

This determination takes about ten minutes.

We have then T and Cl ; V should be accurately measured for the twenty-four hours; the specific gravity should be corrected for the temperature at which it is taken; the determination of W , of course, usually requires that the patient should be able to be out of bed. The valuation of the ratios is then a matter of arithmetical calculation.

Summary.—This paper will miss its object if it does not convey

(a) That the method represents a notable advance in the application of quantitative physico-chemical methods to clinical work.

(b) That the ratio $T \div \text{Cl}$ may furnish information of considerable value in diagnosis and prognosis in cases of cardiac disease and to a less extent in other cases.

(c) That it is distinctly a laboratory method requiring time and care.

In conclusion, it is a pleasure to express my obligation to Prof. E. H. Loomis, of Princeton, for much kind advice as to method, and to Dr. J. J. Walsh, of New York, for the stimulation he gave me to study the subject of my paper.

Soaps, their Chemical Composition and Disinfecting Properties.—F. K. Rosenbach, *Bibliotheca Germanica*, Vol. XII, No. 8, 1912. The author states that domestic soaps are injurious to the skin, inasmuch as they contain a large proportion of free alkali. To be beneficial a soap must be perfectly neutral. The carbolic acid soaps analyzed by him were found to contain from 9.45 to 22.10% of water and considerable free alkali. The amount of carbolic acid in these soaps varied and usually did not come up to the claims made by the manufacturers. Thus, instead of 4% only 1.32% was found; instead of 10% only 2.34%. It was observed that if the soap is made by the cold process from coconut oil the proportion of carbolic acid is more likely to correspond to the label. On the other hand, when the soap is made by the hot process a considerable amount of phenol is lost by evaporation. In the bichloride of mercury soaps a marked discrepancy was found between the statements of the manufacturers and the amount of bichloride actually present. Some samples contained only one-fourth the amount stated on the label. This difference is due to the reduction of the bichloride of mercury which takes place in the soap on keeping. Regarding the antiseptic properties of soap, the author found that plain as well as carbolic acid or bichloride of mercury soap fails to kill anthrax spores in 10 days. The vegetative forms of the colon bacillus are destroyed by plain soap, 10% solution of the latter possessing an antiseptic value equal to 0.3% solution of carbolic acid. The addition of a small amount of bichloride of mercury to a 10% solution of plain soap (0.05% of HgCl_2) does not enhance the antiseptic value of the latter. Bichloride of mercury in the soap seems to lose its antiseptic properties to a considerable extent. Thus, 0.1% of bichloride added to 10% solution of soap is less active than a 0.05% pure solution. The same results were obtained with carbolic acid. This is explained by the fact that these germicides form salts with the fatty acids of the soap, which possess weaker germicidal properties. [A. R.]

A PRELIMINARY REPORT UPON A CASE OF UN- CINARIOSIS (ANKYLOSTOMIASIS.)

By THOMAS A. CLAYTOR,

of Washington, D. C.

Professor of Clinical Medicine, Columbia University, Attending Physician
to Garfield Hospital, etc.

Uncinariosis (ankylostomiasis) is a chronic disease due to infection by a small thread worm known as the *Uncinaria Duodenalis* (*Ankylostona Duodenalis*), which fastens itself to the mucous membrane of the small intestine and sucks the blood from its host. The most prominent symptoms are intense anemia, weakness and dyspnea with anorexia and gastro-intestinal disturbances.

The presence of a genuine case of uncinariosis in this latitude, and occurring in a native American who has spent his life in Virginia, renders the matter worthy of report.

While uncinariosis is extremely common and a very serious disease in many tropical and subtropical countries, it has been diagnosed but rarely in the United States. W. L. Blickhahn *Med. News*, Dec. 9th, 1893) reports a case in a German who had probably brought the infection with him from Germany.

C. H. Tebault, Jr. (*New Orleans Medical and Surgical Journal*, 1899-1900, LII.) reports a case which must have had its origin in New Orleans, and I find in Blanchard (*Zoologie Medical*) reference to articles by Chabert and Duncan in Louisiana, Lyell in Alabama and Georgia, and Heusinger and Geddings in South Carolina, and Little and Leatherman in Florida. Blanchard doubts the authenticity of the last two. I have so far been unable to find the above articles in the Surgeon General's Library, i. e., those referred to by Blanchard.

The importance given to progressive pernicious anemia of late and the impossibility of making the differential diagnosis between it and uncinariosis without examination of the feces for ova is another factor which has led me to bring my case before the profession as soon as possible.

George R., aged nineteen years, of Westmoreland County, Va., occupation, light farm work, was admitted to the Garfield Hospital of Washington, D. C., on May 31, 1901. The history, obtained principally from his sister, as the boy is extremely stupid, is as follows:

Nothing worthy of note in the family history except that there is another brother who also is said to be pale and anemic. The patient was a small baby when born, but developed normally until about three years ago, since which time development has been tardy both in mind and body, his development and appearance at the present being that of a boy under 14 years of age. This point is worthy of note, since it is a characteristic of the disease. "Should serious Ankylostomiasis occur before puberty, the growth and development are apt to be delayed and stunted." Patrick Manson (*Tropical Diseases*). This fact is also noted by F. M. Sandwith. (Observations on 400 cases of Ankylostomiasis" (*Lancet*, Vol. I, 1894).

At school, the boy seemed as bright as any of the other children. He had been employed at light work about the farm until he became so weak that he was obliged to go to bed. He has never had any of the diseases of childhood, nor has he had malaria, which is common in his neighborhood. About three years ago, he became pale; one year later, the anemia became very marked and there was swelling of the face, abdomen, and feet. This condition did not last, however, and he seemed to get somewhat better until this spring. As far as can be learned, there have at no time been any symptoms of gastro-intestinal disturbance, which is contrary to the rule. The boy was sent to the hospital because of his great weakness, pallor, and dyspnea on slight exertion.

The appearance of the patient's face was remarkable, and differed from that seen in any other disease with which I am familiar. The expression was dejected, the skin very pale with a faint yellow tint, not the lemon yellow of pernicious anemia, nor yet the chalky white of advanced nephritis. The face looked bloated, especially about the eyes. The mucous membranes were extremely pale. The body well nourished, but the muscles extremely flabby. The tongue was clean. The heart's impulse was widely diffused, the apex beat was in the fifth interspace and almost as far to the left as the midaxillary line. Over the base there was a loud systolic murmur, the point of maximum intensity being in the pulmonary area. This murmur was also heard in the vessels of the neck. The second pulmonary sound was accentuated. At the apex there was heard a systolic murmur which was transmitted to the axilla and to the angle of the left scapula. A faint diastolic murmur was also present over a small area near the apex. The feet and ankles were edematous. The urine was pale, clear, acid and showed a Sp. g. of 1010 (urine of low sp. g. is the rule in severe cases). Sandwith, *Loc. Cit.* The blood examination, May 31, showed the number of red corpuscles to be 1,577,000 (31% of normal), the whites 4400. Because of an accident to the hemoglobinometer, the hemoglobin was not estimated until four days later, when it was found to be 30%.

Dr. J. B. Nichols, Pathologist to the Garfield Hospital, has kindly furnished me with the following report on the stained coverslips, June 9th: Macrocytes and microcytes, a few; polychromatophilia, not observed; poikilocytes, a few; microblasts, normoblasts and megoblasts, none.

Leucocytes: Small mononuclear, 15%; large transitional, 9%; polynuclear, 71%; eosinophile, 5%; myelocytes, —%.

Under the circumstances it is not surprising that we strongly inclined to the diagnosis of idiopathic pernicious anemia. However, an order was given that the evacuations be examined for the ova of the *uncinaria duodenalis* on the bare possibility that it might be a case of that most unusual disease, at least in the United States, of uncinariosis. Great was my surprise to learn that Mr. Henry M. Jewett, the Assistant Pathologist, had indeed found the object of his search, the ova of the *uncinaria*.

The eggs were so numerous that scarcely a field could be found which did not show several specimens. On June 3d, Thymol gr. xxx, was administered at 3.30 P. M. Two hours later, the dose was repeated and followed in two hours by castor oil, and the next morning by magnesium sulphate. Examination of the evacuations on the 4th revealed 14 *uncinaria*, on the 6th, 23 were found, on the 10th, 7, and as the ova were still present, the thymol was administered as before. Dr. C. W. Stiles, of the Department of Agriculture, confirmed the diagnosis of uncinariosis.

The patient seemed to improve from the date of the first expulsion of the parasites. The edema of the feet and to a marked degree of the face disappeared, and he claimed to feel much better.

The administration of iron and arsenic was at once instituted with a full, nourishing diet. Patient's weight has increased in a week from 85 to 90 pounds and the blood count has also improved slightly.

I wish to express my thanks to my resident, Dr. Bennet and to Dr. Nichols and Mr. Jewett, of the Pathological Department, for their aid and interest in the report of this case, a more complete and detailed account of which I hope to publish later.

Orthostatic Albuminuria.—This condition is the subject of a thesis by Dr. J. Vire, (quoted in *L'Independance Medicale*, 1901, No. 19). It is caused simply by standing. It is found in young people, accompanied by vague vasomotor symptoms only. Under a gram of albumin is found in the urine, accidentally as a rule, generally serum-albumen. Lying down will cause its disappearance. Recovery occurs as the patient grows stouter. It is seen in growing young men or girls who are anemic or nervous. Walking will not often cause it, long standing being the main cause. Vire explains it as a slight vasomotor disturbance in the renal circulation. The treatment is hygienic, strengthening, and anti-nervous. Milk diet is absolutely contraindicated.

THE ROLE OF INFECTION AND INTOXICATIONS
IN DISEASES OF THE SPINAL CORD.

By ALFRED GORDON, M. D.,

of Philadelphia.

Assistant in Neurology, Jefferson Medical College.—Member of
the Philadelphia Neurological Society.

If in the history of medicine the cellular theory reigned a long time, it could not continue to do so with the progress of pathology, bacteriology and chemistry. The clinical observations could no more be in accord in all their aspects with the old views. Behring opened the way for new researches, which led to the discovery in the humoral substances of immunized individuals of chemical principles that now play the most important rôle in the action of antitoxins. Chemistry and bacteriology replaced therefore, the old cellular theory which seemed until recently to be the dominating one. These two sciences brought out very important though complicated points in the life of the cells.

In physiological or pathological conditions the cells present a complicated chemical laboratory of normal or abnormal organic metabolism. A loss of equilibrium in the normal condition of the cell is always characterized by the presence of abnormal chemical substances accompanied by microbes or products elaborated by these microbes—toxins. This last condition we call infection.

To Ehrlich we owe largely what we know of the character of toxins and antitoxins. His theory of lateral chains is remarkable in its simplicity, and explains the phenomena of immunity. According to his views, each protoplasmic molecule of the cell contains a central part essentially necessary to life and controlling the specific function of the cell and lateral chains or receivers. The function of the last is to receive various substances in a dissolved state, with which they enter into chemical combinations and thus take part in the intra-cellular life. The molecules of toxins introduced into the organism are received by some of the lateral chains, and as a result we have the antitoxins. Therefore, between toxins and antitoxins there is a chemical and specific relationship, and the antitoxins constitute an integral part of the cells. That antitoxins, according to Ehrlich, Bouchard and Charrin, are cellular products, and that immunity which they create might persist for years, is proven by Roux and Waillard²: After having bled profusely horses previously immunized so that a new blood was substituted, they observed that the antitoxic power did not disappear.

The microbes or bacteria do not possess the monopoly of producing an infectious disease; their products are also the cause of infection. In order that an infection should take place, two elements are necessary: the infectious agent and the predisposing cause which diminishes the resistance of the organism temporarily, like trauma or cold, or permanently like chronic intoxications (alcohol, lead, etc) and debilitating diseases of long duration.

During a very long time there was a belief that each organ lived separately from the rest of the body, and that its suffering did not have any influence on the rest. An entirely different view is held

now: There is a unity and solidarity among various parts of the living organism; when one organ is affected, the entire system suffers. A bacillus, typhoid, for example, produces a local focus of infection in the intestines, but the toxins circulating in the vascular system will have an influence on the whole economy by means of their chemical combinations with the lateral chains of the cells. The characteristic feature of toxic agents is that each has a special affinity for *certain* protoplasmic molecules and cells of *certain* organs: An infectious agent will attach, with preference, a certain organ primarily, the poisons secreted by it will show their secondary effect throughout the entire system. Whatever the infection is, one is almost certain to find histological changes in many, if not all, organs.

The nervous system, like any other organ, might be attacked primarily or secondarily. Much has been accomplished in regard to infections in diseases of other organs. The attention directed towards the chemical reactions which take place in the living cells, the discovery of toxins and antitoxins within the cells, the logical consequence of prophylaxis in infections, and the great question of serotherapy—all the benefit derived from these studies were almost exclusively applied to infections localized primarily in any organ except the nervous system. In reading very attentively the histories of a great number of cases of diseases of the spinal cord, the writer was impressed with the lack of etiological causation. It is remarkable how many writers report histories of their cases without the slightest attempt to elucidate the etiological factors, or if one or two points in that direction are mentioned, they are not at all taken in consideration, and no relationship is found between them and the disease itself. We endeavored to investigate the etiology of all the diseases of the spinal cord coming under our observation at the hospital, and almost in every case we were able to detect some infection passed unnoticed by the patient or his physician, whether it was a mild attack of measles, or a plain cold, or some febrile condition, a malaise due to auto-intoxication. In reading up the histories of cases recorded, we could find in a good number of them some infection in connection with the onset of the diseases. I do not speak exclusively of the secondary intoxications produced by certain modifications manifested in other organs, which are due to some perturbation of the whole nervous system by virtue of the presence of toxins in circulation. We also have in view the initial attacks of infections on the spinal cord, like, for instance, the primary effect on the cord of tubercular, typhoid, gonorrheal, diphtheritic infections, etc. We mentioned above that some toxic agents go directly to some organ primarily and enter into chemical combinations with certain lateral chains of certain cells. If it is true of any other organ, it is also true of the spinal cord, and this we will endeavor to prove with clinical as well as pathological facts.

Considering the nature of the phenomena which characterize an infection, we see that an intoxication takes place by means of microbes. The very first and constant result is inflammation, which represents the reaction of the organism against the intoxication. The spinal cord presents a feeble organic resistance; moreover, it seems to us that intox-

²Read before the Philadelphia Neurological Society, March 25, 1901

ications produce more deleterious effects on the spinal cord than on any other organ. An acute infectious intoxication of the spinal cord is characterized by a primitive alteration of the nervous tissue, consisting of congestion, but with a toxic vascular exudation, the contact with which is sufficient to produce foci of necrosis, hemorrhages; sclerosis follows almost inevitably. The difference between a new and an old inflammation is that in the first case we shall have an immediate and rapid reaction, whereas, in toxic lesions, due to an old inflammation, we shall have no general reaction and less rapid involvements, but the result will always be identical. If inflammatory changes are the result of infection, are all the diseases of the spinal cord due to inflammation, and if it is so, are they all due to infection? In their studies on the pathogenesis of *multiple disseminated sclerosis*, Charcot and his pupils considered the disease as a primary and chronic inflammation of the interstitial tissue. Rindfleisch,³ on the contrary, placed the initial lesion in the walls of the vessels, while others believe that the nerve element is first affected and interstitial inflammation is secondary; but most authors, according to Strumpel, consider it as a primary disease of the vessels. As to the etiology, Ebstein⁴ was first, who, after a clinical and pathological investigation on a man 44 years of age, who died from typhoid fever, found the effects of the infectious disease on the spine, expressed in a disseminated sclerosis. Later, other observations were added,⁵ and they all tend to prove that microorganisms, with their chemical products, are apt to produce a disseminated sclerosis. The chemical combinations found in the toxins are numerous; we find carbonic acid, hydrogen sulfide, ammonia gas, etc. On the other hand, cases of multiple sclerosis were reported as a result of intoxication with carbonic acid gas.⁶ This gives us a clue to explain the fact why an infectious disease might give place to multiple sclerosis. Not only typhoid infection is the cause of multiple sclerosis, but also other infections. Cases reported by Schoenfeld⁷ prove to be true. Marie observed the same after typhus, variola, scarlet fever, measles, dysentery, pneumonia, Charcot after cholera and diphtheria. Wispham⁸ observed clinical symptoms of multiple sclerosis after variola, and as the patient improved, although very slowly, he called it false disseminated sclerosis. The same type of sclerosis was observed by Marie after typhoid fever,⁹ by Sparks after whooping-cough,¹⁰ and after grippe,¹¹ by Stadhagen after diphtheria,¹² by S. Lotsch,¹³ after lung infection (2 cases), after typhus (4 cases), after influenza (1 case), by D. Williams,¹⁴ after measles, by Colcott,¹⁵ after some eruptive disease. Lannois and Paviot¹⁶ report a case of multiple sclerosis subsequent to tubercular arthritis of the shoulder. Rendu¹⁷ reports a case of transitory hemiplegia, followed by symptoms of disseminated sclerosis, which developed after some infection. Four years later the patient died, and the autopsy corroborated the diagnosis. Multiple sclerosis, with symptoms of *progressive muscular atrophy* after influenza, is reported by Hammond.¹⁸ In *Landry's paralysis* we always find a history of infection. Although the pathological findings are various as to the localization, they always show engorgement

of blood-vessels, exudation, foci, in one word—inflammation produced by an infectious agent. In the cases reported by Knapp-Thomas¹⁹ was always a condition of some infection. The same we find in Langdon's case.¹⁹ Spiller¹⁹ reports a case of Landry's paralysis occurring after an abortion which was followed by a purulent uterine discharge. O. Soltman²⁰ reports a case beginning with symptoms of infection. Boinet²¹ reports a case of a man who suddenly took cold and developed the disease; microscopical examination revealed vacuoles in the ganglion-cells, thickened meninges, nerve-fibers in a state of degeneration; bacilli were found. Kapper²² reports a case of Landry's paralysis due to auto-intoxication (dyspepsia). Remlinger²³ reports a case due to streptococcus: A soldier in the Colonies had previously malarial fevers. All of a sudden he was taken with paraplegia; a typical Landry's paralysis developed. The microscope showed: inflammation and dilatation of blood-vessels of anterior horns, streptococci in the parenchyma of the anterior horns between the cells. Baumgarten, Curschman, Eis-enlohr, Cantanni, Marinesco and Marie—found in the cord various microbes, as bacillus anthracis, Eberth's staphylococci, streptococci. In *anterior poliomyelitis*, Marie thinks, that the cause of inflammation lies in an infectious virus and commences in the blood and vessels; the degeneration of the cells is a secondary phenomenon. The whole clinical picture of this disease points to the presence of an infectious element. In Sinclair's²⁴ case it was due to a cold. Dercum²⁴ speaks of a child who, after a series of infectious diseases, as rubeola, varicella and scarlatina, sustains a trauma and develops the disease. In *muscular atrophies of spinal type*, we often find a history of some acute infection or chronic intoxication. G. Campbell²⁴ reports a case of a man who had several attacks of sciatica and was also alcoholic: developed the peroneal type of the disease. W. J. Morton²⁴ speaks of a man who contracted fevers in Africa, had chills and developed a multiple neuritis with atrophy, fibrillary twitchings, exaggerated K-J. Muscular atrophies of spinal type were seen following gonorrhea. Limasset²⁵ published 12 cases, Spillman and Haushalter²⁶ refer to two cases of spinal manifestations with muscular atrophies due to gonorrhoeic infection. Sulzer²⁷ reports a case of bilateral Erb's scapulohumeral palsy with atrophy due to fever with suppurative inflammation of ilio-cecal region. Tubercular infection might also have its effects on the spinal cord. Two cases were published in *Deut. Zeitschr., Nervenheilk.*, 1899. One is a case of a 9-year-old boy, where the tuberculous changes were characterized by inflammatory changes of arteries and veins of the dura, pia, infiltration along the vessels in the white substance and cells, swollen axis-cylinders. The second case of a two-year-old child presents the same changes. Decroly²⁸ reports a case of multiple neuritis with spinal involvement of tuberculous nature: complete palsy of the muscles of the leg with atrophy and RD, loss of K-J, Aran-Duchenne's type of atrophy. A similar case was reported by Finizio,²⁹ who found outside of other lesions involvement of the cells of the anterior horns. Cases of *ataxia* of spinal character were reported after measles by Colcott Fox,³⁰ after scarlet fever by Bruns,³¹ after

typhoid fever by Clement,³² and Kühn,³³ after mumps by Munro and Healy,³⁴ after influenza by Tumpowski.³⁵ If we now consider the natural history of *myelitis*, it seems to us that its infectious origin is an established fact. Its vascular and infectious nature is proven beyond doubt. At the last Congress of Paris, this question was brought up by various authorities with pathological and bacteriological proofs in favor of it. Marinesco found in two cases the streptococcus, in one case—pneumococcus, and in one—bacillus anthracis. His conclusions in regard to Landry's paralysis, are that the last is dependent upon an infectious ascendant and descendant myelitis. Meyer³⁶ reports a case of a cellulitis and subsequent meningitis with streptococcus, where, apart from various lesions of the brain, he found unilateral lesions of the cord in the region corresponding to the muscles affected: multiple degeneration of the cells. Dogliotti³⁷ reports a case of an abscess of the right half of the medulla due to onychia of the right thumb; cultures showed staphylococcus aureus. Leprous infection was found to show its effect on the spinal cord. Homen³⁸ saw two cases of lepra which produced lesions of the cord approaching those of *Tabes*. So did Lésage and Thiercelin.³⁹ The microscope showed a total degeneration of columns of Goll and of the septomarginal tract; the walls of the vessels were thickened and veins presented inflammatory thrombosis. Colella and Stanziale³⁹ found in a case of leprosy foci of myelitis. Looft³⁹ found atrophy of the sensory roots, sclerosis of spinal ganglions, and much pronounced degeneration of posterior columns. Jeanselme³⁹ found degeneration of Goll's columns and septomarginal tracts. Babés,³⁹ in 22 autopsies, found Hansen's bacilli in anterior horns; the chromatin was broken up, cells presented vacuolation. In Pellagra, Marinesco³⁸ found the cells of Clarke involved, degeneration of the pyramidal and anterolateral tracts. In a case of diphtheritic paralysis, L. Richon,⁸ found lesions of the cells of the anterior horns, atrophy with disappearance of the chromatin, involvement of the roots. Clark's cells were globular. Crocq³⁸ studied the histological changes of the nervous system in a dog suffering from rabies, and at the same time in different other infections, and arrived at the conclusion that rabies is an acute myelitis. *Transverse lesions* of the spinal cord were studied by Bastian:⁴⁰ in two cases secondarily to cancerous tumors of the breast, in one case following smallpox, and in one case after some unknown infection. The microscopical pictures were almost all identical as to the character of infectious inflammation: softening of the cord, great vascularity, descending and ascending degenerations. In a case of tetanus, Marnesco⁴¹ found diffuse hemorrhage in the gray matter, change in the chromatin of the cells, degeneration of the white matter. The lesions produced by syphilitic infection are too common and too well known to dwell upon. The syphilitic agent or its toxin is carried by the blood like in any other infectious disease. In addition to the direct effect of this specific toxin upon various portions of the cord through the blood-vessels, there is another point to be considered. It happens that the obnoxious specific agent reacts in a latent manner, as, for example, in para-

syphilitic lesions, and we have a weakening of the whole nervous system in its nutrition and its power of resistance. According to the most modern views pernicious anemia is supposed to be the result of an hypothetical poison. If the spinal cord becomes involved, the following changes similar to those of infectious spinal diseases were found: dilatation of perivascular spaces, which are filled with leukocytes, thickened walls of the vessels, foci of acute myelitis, proliferation of vessels, degeneration of posterior columns (Homén). E. Bloch⁴² reports a case of an eight-months' child suffering from leukemia, where autopsy showed myelitic foci followed by degeneration of fibers with diffuse sclerosis and increase of neuroglia. Lichtheim⁴³ considers diseases of the spinal cord in pernicious anemia as due to some toxic agent, and finds degenerative foci. The writer contented himself in presenting but a few examples. If one takes the trouble to read the literature for the past few years, he will be surprised to see how large is the number of spinal diseases caused by infection; and if the histories reported were read or taken carefully, one would almost always detect some infection as etiological factor. The clinical and pathological conditions of cases, where infection is not mentioned, and of those where it is stated, are identical. The microscope gives the same picture: inflammation, with all its consequences, is present. Let us turn our attention for a moment to experimental medicine in this field. Myelitis was produced by Roux in 1883 with toxins of rabies; by Babinski and Charrin, in 1888, with bacillus pyocaneus; by Roux and Yersin, in 1888-1889, with diphtheritic bacillus; by Gilbert and Lion, in 1888 and 1892, with bacteria coli; by Vincent, in 1893, with typhus bacillus; by Ballet and Lebon, in 1895-1896, with diplococcus of pneumonia. Autopsies in all these experiments showed vascular alteration in the first place, hyperemia, hemorrhages, foci of myelitis, alteration in the gray matter, degeneration in the white matter, proliferation of neuroglia. Bourges⁴⁴ experimented on a dog with streptococcus erysipelatosus and obtained the clinical pictures of amyotrophic paralysis, and at autopsy, myelitis with alteration of cells. Vidal and Berzancon⁴⁵ inoculated in the blood-vessels cultures of streptococci of various origin, with the result that paralysis took place, and at the autopsy they found diffuse degeneration mostly in the anterior horns. Morel and Rispal,⁴⁶ in a case of experimental myelitis with a culture of streptococcus, found bacteria in vessels, anterior horns and central canal. As to bacteria, it seems to us that it is not sufficient to look for them only in sections, because one might not find them, but also cultures should be made; the last procedure is more correct and rapid. Remlinger, in the case mentioned above, could not see the streptococcus in dorsal and lumbar sections, but did obtain them from cultures. Homén and Laitinen,⁴⁷ in their studies of the influence of streptococci and their toxins upon the spinal cord, described the following observation: hyperemia, hemorrhages in the first place, infiltration of leucocytes in the spinal ganglia, change of nerve fibers and neuroglia; anterior cells are destroyed in lumbar region, fibers become degenerated; bacteria in the cord in the first

five days; streptococci reach the spinal cord through lymphatic spaces of posterior roots and fill up the intermeningeal spaces of the whole cord; the pathological effect of injections of bacteria or their toxins is the same. Remlinger⁴⁸ produced an experimental muscular atrophy with paralysis by means of a sterilized culture of pneumococcus; 12 days after the injection he observed in a rabbit symmetric atrophy of the muscles of the shoulder and anterior extremities; 8 days later—complete atrophy. Carriere⁴⁹ described a case of myelitis due to pneumococcus, with autopsy. Ballet and Lebon produced a paraplegia with injections of cultures of pneumococcus. Moltchanoff⁵⁰ experimented on mice with cultures of gonococcus, and obtained an acute ascending paralysis; autopsy revealed that the cells of the anterior horns presented an acute degeneration and vacuolation. We, therefore, see that the pathological aspect of experimental diseases of the spinal cord is identical with that we mentioned above. Here and there inflammation is the first phenomenon, and the other lesions are a natural consequence of it. If we wish now to characterize the nature of the phenomena of infection, we must say that the microbes always show their effect through a process of intoxication. If, on the other hand, we give a glance at the lesions produced in the spinal cord by poisons of organic or inorganic chemical bodies, we find identical phenomena of intoxication. Lead, alcohol, arsenic, mercury, etc., introduced into the system, are capable of producing the same lesions in the spinal cord as intoxications due to microorganisms. We often observe that in chronic intoxications due to lead or alcohol, the blood and the tissues being chronically in contact with the poison are so altered that any added acute microbic infection gives an immediate and easily produced affection of the spinal cord. Any trauma or cold in an individual with a lowered resistance will aid the development of an infection; sometimes even without any apparent exciting cause, these poisons give place to the same phenomena. It is a question in my mind whether the lesions are produced directly by these organic or inorganic intoxications, or, rather, by some microorganism which has found a favorable ground to develop. Homén found in seven cases of alcoholism changes in Goll's columns and Lissauer's tracts, but always a thickening of the walls of the vessels and diffuse sclerosis. Bastian (*loc. cit.*) reports a case of an alcoholic who subsequently to an insignificant trauma within two years developed tremor, pain in the back, involvement of the sphincters. Autopsy showed that the dorsal cord was very vascular and soft; there was also ascending degeneration. Lead intoxication gives almost identical results. Onuf⁵⁰ reports a case of a painter who had a fall; later he became suddenly ill, and in three days developed paralysis of the lower extremities and left arm. Autopsy showed poliomyelitis of the anterior horns, infiltration of blood-vessels and involvement of the anterior roots. A case of *amyotrophic lateral sclerosis* due to lead intoxication was reported by Ch. T. Potts.⁵⁰ Mercury and arsenic are apt to give rise to the same symptoms. Donetti⁵¹ and Gilbert⁵² report cases of tabes due to intoxications with these two minerals. Lesions of the spinal cord might be due to toxins not intro-

duced from the outside world. I speak of so-called auto-intoxications. Alteration of blood, toxic or any irritative substance developed secondarily to digestive disturbances give place to auto-intoxication, which is apt to predispose to some degenerative condition of the cord. Sedentary life, mental and physical strain, are likely to bring on an intestinal atony; various toxins, like scatol, indol, etc., develop and are carried to the spinal cord through the lymphatic system. Feinberg⁵³ reports a case of asthenic bulbar paralysis following auto-intoxication due to obstinate constipation. Lichtheim (*loc. cit.*) speaks of a case of diabetes and of three cases of grave icterus, followed by spinal symptoms. Sougues and Marinesco⁵⁴ found at the autopsy of a woman, who died from diabetes, degeneration of the posterior columns. They express an opinion that the lesion of the cord is due to toxins of auto-intoxication. Ettlinger and Nageotte⁵⁵ produced an experimental Addisonian auto-intoxication and found in the spinal cord changes similar to infectious alteration. The preceding study permits me to arrive at one conclusion, that whether the diseases of the spinal cord are due primarily or secondarily to a microbe introduced from the outside world, to organic or inorganic intoxication, or to auto-intoxication—the general term that we could use to express the effect, is *intoxication*. As soon as the organism is attacked, it begins to defend itself by means of its cellular secretions. The cell can triumph over the pathogenic agent only when it contains ferments capable of digesting and destroying that agent. The leukocyte is not the only cell that contains phagocytic elements; there are other cells that produce chemical substances for protection against the enemy. The antitoxins meet in battle the toxins and render the organism indifferent to their influence. As soon as infection sets in, these antitoxins begin to be formed in Ehrlich's lateral chains, and the morbid condition will be shortened or prolonged, aggravated or attenuated, according to the amount of the protective substance. When the disease is conquered, profound chemical modifications take place in the system and produce *immunity*. These modifications depend upon the accumulated toxins and production of defensive substances. The therapist's duty is to combat the effect of toxemia by helping the destruction and elimination of toxins, and at the same time to stimulate the defensive reactions and therefore increase the resistance of the organism. The last can be accomplished by *serotherapy*, which has already given such admirable results in many cases. This method does what the organism should have done; it provides with substances which the enemy had not time yet to produce; it shortens the course of the disease, and in some cases succeeds in arresting it. It is permitted to hope that serotherapy will be utilized in all sorts of infections. For that it is necessary that we should be completely familiar with the evolution of infectious processes, and in all cases succeed in finding the primary cause of a given infection. The nervous system in general and the spinal cord in particular can be attacked by infections secondarily and primarily. The writer firmly believes that it takes place more frequently than it is generally thought, and that infections and intoxications of

various character present in diseases of the cord the most frequent and the most active causative element. Since his attention was directed to it, he finds an infectious element or some intoxication almost in all the cases with which he comes in contact. The examples presented by him from the literature, clinical, pathological and experimental, are very few, indeed; in reality they are numberless. The object of this essay is to plead for a more thorough investigation in etiology of diseases of the spinal cord and apply the same principle in treatment as in diseases of any other organ of an infectious nature. Serotherapy has accomplished a great deal in therapeutics, and the day is not far distant when it will be applied in diseases of the nervous system. It is not sufficient to treat the symptoms, one must ascend to the initial cause.

JOURNAL DES PRATICIENS.

April 20, 1901. (15m. Année, No. 16.)

1. Cardiac Asthma. M. MERKLEN.
2. Enteroposis. FRANTZ GLÉNARD.
3. The Pest in Alexandria in 1899. VALASSOPOULO.

1.—**Cardiac asthma** may occur in small attacks or in larger paroxysms. The smaller attacks are seen in almost all cases of cardiac insufficiency. They occur suddenly at night, on account of the greater tendency to venous stasis at that time, with dyspnea lasting at most a half hour. They generally reappear night after night, rarely twice in one night. These attacks are seen in cases of mitral insufficiency with loss of compensation, and in cases of advanced arteriosclerosis with cardiac dilatation, myocarditis, and renal insufficiency. When the aorta or coronary arteries are affected, the attacks may resemble angina

pectoris. The larger paroxysms occur at night, too, with intense dyspnea, lasting several hours. Anginoid pain may be felt with these, or edema of the lungs may follow, with expectoration, due to aggravated venous stasis. Asphyxia may come on. Pulmonary edema is commonly seen in those with arteriosclerosis or kidney disease. Cardiac asthma has been theoretically explained as due to sudden weakness of the left ventricle, to renal insufficiency, or to toxins absorbed from the gastro-intestinal tract. In the paroxysms, Merklen advises counterirritation, with bleeding should pulmonary edema exist. Heart stimulants will be needed, and morphin with ether, hypodermically. For the smaller attacks digitalis or chloral can be given. Theobromin may also do good. Rest with diet and care will effect excellent results. The iodides should only be given guardedly. [M. O.]

2.—In his third and last lecture upon **enteroptosis**, Glénard defines enteroptosis as a disease characterized by the signs and symptoms of ptosis of one or more abdominal viscera. It may be primary or secondary. Among the predisposing causes he places corsets, parturition, long standing, laparotomy, liver disease, nervous disease, etc. The exciting causes may be traumatic, puerperal, infectious, toxic, or nervous. Enteroptosis may appear in four different forms, gastro-intestinal, lithemic, neurasthenic, or cachectic. It passes through three stages, the gastric, mesogastric or hepatic (lithemic), and neurasthenic or cachectic. If no diagnosis be made, the duration will be indefinite; otherwise its duration depends upon the treatment. The diagnosis is easily made from the symptoms, which are again fully described. An abdominal binder must be worn, saline laxatives and alkalies given, and a strict diet observed. Cold douches, massage, static electricity, etc., will also aid in treatment. The prescriptions and a full diet list follow. [M. O.]

3.—In May, 1899, the pest appeared in Alexandria. The rats had already been affected. In one grocery over 200 dead rats were found. Cases were found all over the city. During the three months epidemic, 92 cases occurred. In all but one case there was little fever. About the fourth or fifth day the temperature fell to normal as a rule, with perspiration, diarrhea, etc. Then the patient began to improve, or complications were noted in a few days. The buboes suppurated in from 7 to 10 days, without fever. One case began with vulvovaginitis due to the pest bacilli. Pest-pneumonia occurred, both primary and secondary, as did the gastro-intestinal form. Buboes should be incised, with care, under chloroform, when decided fluctuation has appeared. Yersin's serum treatment was tried in 11 cases, with 7 cures. The Haffkine prophylactic serum confers about three weeks' immunity, but causes marked reaction, both local and general. Valassopoulos prefers using 5 c.c. of the Yersin antipest serum, which causes much less reaction. While pest may occur in the individuals inoculated, it is always attenuated in character and they recover eventually. [M. O.]

On the Disturbances of Speech in Intermittent Fever.—

I. E. Tilanadze (*Bobnitchnaya Gazeta Bakova*, Vol. XII, No. 13) reports 3 cases of malaria in which disturbances of speech occurred during the attack. In one aphasia developed without any other involvement of the nervous system; in the second the aphasia was accompanied by paralysis of the right upper extremity, while in the third there was only stammering. The conclusions drawn by the author from his own cases and those collected from the literature are as follows: (1) The disturbances of speech mostly observed in malaria occur in the form of atactic aphasia. (2) A simple difficulty of speech or stammering is of rare occurrence. (3) Disturbances of speech are more frequently observed in connection with the malignant forms of the disease. They occur either together with the paroxysms or at the height of the disease; rarely at the end of it. (4) Malarial aphasia is more frequent in man than in women. (5) It is frequently accompanied by paralysis. (6) Malarial aphasia is usually temporary, is of short duration and entirely recovered from. [A. R.]
